Last week several of the newspapers gave accounts of the temporary recovery of a newborn child supposed to have been stillborn, and that after its exposure to a cold-storage temperature for a considerable length of time. The story appeared preposterous, but a well-known physician who holds a public office the duties of which call him frequently to the morgue assures us that in its main statements it is true. It seems that two newborn twins, to all appearances dead, were brought to the morgue by their father. They were at once put into the cold receptacle—so cold, our informant tells us, that when it is opened for a few minutes the bystanders feel like buttoning up their coats. After a while one of the employees heard proceeding from the inclosure sounds which he thought might be made by mice; then the sounds grew louder and seemed to him to be those of a cat. Curiosity led him to investigate, and he found that the cries came from one of the infants, although it had been exposed for a long time, certainly more than half an hour, to the intense cold. The child, about whom there was no warm wrap, was rescued at once and sent into Bellevue Hospital, where its full resuscitation was accomplished. Unfortunately, however, it lived only a few hours. Surprising as it is, we do not think this occurrence need worry those persons who rely on the undertaker’s refrigeration as a safeguard against burial alive.

ROSE SPOTS IN A CASE OF INFLUENZA.

As is well known, considerable diagnostic importance is attached to the rose spots of typhoid fever. Although, of course, the absence of that disease does not necessarily preclude the appearance of such macular, their presence in a case at all suggestive of typhoid fever, but of a different nature, may well be embarrassing. Such a case is reported by Dr. E. Feindel and Dr. P. Froussard (Gazette des hôpitaux, 1898, No. 62; Centralblatt für innere Medizin, October 21, 1899). Two trials of the agglutination test proved negative, one during the stage of full development and the other during convalescence, and the authors held to the diagnosis of influenza.

MULTIPLE OCULAR MANIFESTATIONS OF SYPHILIS.

While isolated ocular complications in syphilis are not uncommon, a case recorded by Dr. Lor (La Clinique, Bruxelles, July 29th; Journal de médecine de Paris, October 1st) shows an unusual variety of such complications. Within a year of the initial chancere Dr. Lor’s patient displayed in the order given the following series of ocular symptoms: Optic neuritis with internal opthalmoplegia (paralysis of the iris and of the muscle of accommodation) in the left eye; papule of the ocular conjunctiva and lacrymal obstruction; double seropapular iritis; and interstitial keratitis of the left eye.

NASAL OBSTRUCTION DUE TO A LEECH.

In our issue for October 7th we cited from the Lancet a case of epistaxis due to a leech in the nares. Dr. Lim Boon Keng, of Singapore (Scottish Medical and Surgical Journal, October), records the case of a Japanese workman who had all the appearance of having recently lost a large quantity of blood. A leech had got into his nostril about three months before while he was bathing. A forceps was applied to the leech, which, however, held on so firmly that traction was abandoned. Syringing the nostrils with potassium permanganate lotion only made the animal contract more firmly. Finally the patient was caused to inhale a few drops of chloroform by each nostril, when it relaxed its hold and fell with the forceps to the floor. Dr. Keng suggests that probably a better way would be to inject a few drops of chloroform into the body of the leech with a hypodermic needle. This will recall a recent suggestion as to the hypodermic injection of morphine into a protruding tapeworn.

RED SPECTACLES FOR SEASICKNESS.

The Canadian Medical Record for October quotes the Scientific American as saying that bright red spectacles accompanied by the internal administration of calomel form a new German specific against seasickness. It is deduced from Epstein’s investigations on the influ-
ence of color on the blood-vessels in the brain. Seasick-
ness is due to lack of blood in the brain, while red sends
blood to the brain with a rush. By looking at one point
for some time through the red glasses the patient is
cured radically. This seems like one of those things
that are said to be evolved out of the inner conscious-
ness; yet it is not altogether improbable, and its truth
or falsity should be easily susceptible of definite settle-
ment.

THE EFFECT UPON THE UTERUS OF EXTRATION
AND TRANSPLANTATION OF OVARIES

A series of twelve experiments performed upon rab-
bbits by H. Rubinstein (St. Peters burg medicinische
Wochenschrift, 1899, No. 31, p. 281; Presse médicale,
September 20th) gives results that have a bearing upon
removal of the uterine appendages. In twelve rabbits
the ovaries were excised, and they were left free in the
abdominal cavity in seven of them, while in the other
five they were grafted at some point on the peritomium.
After some time the animals were killed and a histologi-
cal examination made of the uterus with the following
results: In those cases where the ovaries, whether left
free in the peritoneal cavity or grafted on to the perito-
neum, had been resorbed, the uterus presented the clas-
cic lesions of atrophy from castration—that is to
say, atrophy of the mucous and muscular layers, thick-
cuing of the vessels and proliferation of connective tis-
seau in all the layers of the uterine wall. On the other
hand, in those cases where the ovaries had taken root
and continued to exercise their functions this atrophy
did not take place. From these facts the author con-
cludes that the atrophy of the uterus supervening upon
ablation of the ovaries is not due to the destruction of
the circulatory and nervous connections between these
organs, but to the abolition of the ovarian secre-
tory function.

INFLUENZA AND POST-NASAL ADENOIDIS.

With its own inherent dangers and its protein and
horrible sequel, influenza is one of the notable plagues
of the last few years. That is all the more reason to
be thankful that in a few instances it has proved ben-
ficial by causing the rapid disappearance of adenoid
growths in the vault of the pharynx. Several cases of
this occurrence are reported by Dr. Chauveau (France
médicale, September 1st; Lancet, October 21st).

EXPRESS COMPANIES AND SAMPLES.

Several times a year, for a decade or longer, a phy-
sician living in the Twenty-sixth Ward of the borough
of Brooklyn has received notice by mail, from the manu-
facturers of dietetic and medicinal preparations, to the
effect that they had sent him samples of their goods
and asking his opinion on their merits. In only two in-
stances, to the best of his recollection, have the articles
reached him when sent by express, nor has he ever re-
ceived a notice from an express company that a parcel
directed to him was in its possession and might be
called for. Articles sent by mail have always arrived.
As the doctor did not wish, for various reasons, to seem
desirous of receiving such samples, he has generally re-
frained from notifying the senders of these articles
of their non-arrival; but he is beginning to take a new
view of the subject, and hereafter every non-delivery
will be reported, in order to guard the makers or venders
against something that is certainly an imposition if not
worse. In this great country, with its enormous ex-
press business, the value of articles thus miscarried, in-
cluding the money paid in advance for their carriage and
delivery, may amount to an immense sum in the
course of a year.

AGAIN TO THE DOCTOR IN GENERAL LITERATURE.

The recently published Life of General Nathan
Bedford Forrest, by Dr. John Allan Wyeth, is a con-
scious example of what might often be expected of
the educated and thoughtful medical man did not the
greater number of us become narrowed by the demands
of practice and live only in and for the “shop.” The
book represents years of research; in fact, ever since
the closing years of the civil war, when Dr. Wyeth
served in a regiment under Forrest’s command, he has
been a student of Forrest and his career. The value
of the work is very great, both historical and literary.

THE TERM SIRIASIS AND THE DOG STAR.

There has lately been a tendency to revive the old
term siriasis as the name for insolation. Dr. Kenneth
Macleod (British Medical Journal, September 9th) ob-
jects to it as “more or less mythological,” and goes on
to show the “very infirm foundation” of the hypothe-
sis of the connection between sunstroke and the dog star.
His objection seems to be somewhat unnecessary, for
the word siriasis is not derived from Sirius, but from σκηλός, to be hot.

ITEMS.

Infectious Diseases in New York.—We are indebted
to the Sanitary Bureau of the Health Department for
the following statement of cases and deaths reported
for the two weeks ending November 4, 1899:

Digestive Value of Hearty Laughter.—Hippocrates,
says the Virginia Medical Semimonthly for October
13th, recommended eating at table with others, and
the making of conversation as gay as possible, since hilar-
ity and laughter were the greatest aids to digestion.
This he believed was a happy and rational application
of physiology, of which the stomach derived the greatest
benefits. Not long ago, a gentleman excused himself
at the last moment from attending the theatre, on the
plea that he had then a violent attack of indigestion.
“Go,” said his physician friend, “by all means go, as
nothing will so surely and quickly cure you as a good
hearty laugh.” The play was a broad farce, full of
ridiculous situations, from start to finish, and the result
proved the wisdom of the doctor’s suggestion. Long
before the first act was over, the patient said he never felt better in his life.

The Buffalo Academy of Medicine.—At the last regular meeting of the Section in Surgery, on Tuesday evening, the 7th inst., Dr. Herman Mynter read a paper entitled The Pathology and Pathology of Appendicitis, and their Bearing on the Treatment.

Changes of Address.—Dr. E. F. Arnold, to No. 30 West Thirty-second Street, New York; Dr. Andrew F. Carrier, to No. 321 Lexington Avenue, New York; Dr. A. B. Townshend, to No. 33 West Thirty-third Street, New York.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, and plague were reported to the Surgeon-General during the week ending November 3, 1899:

BIRTHS, MARRIAGES, AND DEATHS.

Married.

BOSTWICK—STUART.—In Beaufort, South Carolina, on Wednesday, October 25th, Mr. Henry F. Bostwick and Miss Mary Darmwell Stuart, daughter of Dr. Henry M. Stuart.

CHALLENGER—BIXBY.—In Concord, Massachusetts, on Thursday, October 19th, Dr. Theodore Challenger and Miss Anne Locke Bixby.

De BOEVOSE—PILCHER.—In Brooklyn, on Wednesday, November 1st, Captain Charles I. De Boevoise and Miss Sara Fiske Pilcher, daughter of Dr. Lewis S. Pilcher.

JERVEY—SMITH.—In Charleston, South Carolina, on Thursday, October 26th, Dr. James Wilkinson Jervy and Miss Helen Doremus Smith.

KITTEN—DAVENDO.—In Ghent, New York, on Thursday, October 26th, Dr. Martin M. Kittell, of Kinderhook, New York, and Miss Davenport.

RAMAGE—PERCY.—In West Feliciana, Louisiana, on Wednesday, October 25th, Dr. Charles Lewis Ramage, of Winniboro, Louisiana, and Miss Rowena Hereford Percy.

STORER—AYRAULT.—In Geneva, New York, on Thursday, October 31st, Dr. Malcolm Storer, of Boston, and Miss Grace Ayrault.

Died.

BATTLE.—In Asheville, North Carolina, on Sunday, October 29th, Alice Maude Battle, wife of Dr. S. Wistay Battle, United States Navy, retired.

BIENVENU.—In Hahnville, Louisiana, on Wednesday, November 1st, Marie Felicie Bienvenu, wife of Dr. Delphin Bienvenu.

Bleecker.—In Whitestone, Long Island, on Sunday, November 5th, Dr. Edward Bleecker, in the fifty-sixth year of his age.

DONOVAN.—In Troy, New York, on Friday, October 27th, Dr. Daniel D. Donovan, in the twenty-ninth year of his age.

DRURY.—In Brooklyn, on Wednesday, November 1st, Dr. Alfred T. Drury, in the seventy-seventh year of his age.

PARREE.—In New York, on Friday, November 3d, Dr. Charles Inslee Parrée.

TAYLOR.—In Tangipahoa, Louisiana, on Tuesday, October 24th, Dr. W. C. Taylor, formerly of Amite, Louisiana, in the seventy-fifth year of his age.

VON GOHREN.—In Bay St. Louis, Mississippi, on Thursday, October 26th, Caroline Von Gohren, wife of Dr. Ludwig H. Von Gohren.

WOODBRIDGE.—In Williamsburg, Massachusetts, on Friday, November 3d, Dr. Luther D. Woodbridge, of Williams College.

Letters to the Editor.

BLUE BOTTLES VERSUS RED BOTTLES.

FORT SILL, OKLAHOMA TERRITORY, October 26, 1899.

To the Editor of the New York Medical Journal:

Sir: Why do physicians and pharmacists use blue bottles for medicines which are likely to be decomposed by light? Everybody who knows the first principles of
physics knows that the blue rays of the solar spectrum are near the actinic rays, and the red rays are the non-actinic rays. This is a subject which seems to me one that should be agitated. If Aristotle used blue bottles in his drug store two thousand years ago this is no reason why we should continue the practice when we know that it is wrong. Photographers use red envelopes for mailing proofs, showing that they pay attention to this subject. I recently had a negative taken by a photographer. A few days afterward he sent me the proof in a non-actinic (red) envelope. The same day a man came to me with acute trachoma, wearing blue glasses, which had been ordered for him by a physician. I went to the dispensary to have a solution of silver nitrate prepared. There was no colored phial, except a blue one. I looked around for a piece of red paper to cover the phial, but all the paper was blue, too. New dispensing sets are being sent out with blue bottles for medicines which are decomposed by light. I hope you will call the attention of the profession to this matter through the columns of the Journal.

First Lieutenant and Assistant Surgeon, United States Army.

M. M. Cloud.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL.B.

XLIV.

CRIMINAL LIABILITY.

(Continued from page 684.)

Conditions Existing Subsequent to Alleged Operation Admissible.—Facts and conditions existing subsequent to the alleged operation, but which tend to explain the patient’s condition, are also relevant and may be shown upon trial. It was accordingly held proper to permit a witness to state that she had been sent for the day before deceased’s death to wash her and change her clothes, and that she found blood stains upon the bed and clothing, and that there was a peculiar offensive odor which she had never noticed before at any time or place, although she had noticed something like it.* And so, a witness was permitted to testify that about the middle of February (the operation being alleged to have been committed about the middle of January) she slept one night in the same bed with the complaining witness, who looked unusually pale and feeble, and sighed and groaned a good deal; that the witness made the bed next morning and saw red stains upon it, through the feather bed and upon the straw bed, which she thought were quite recent, and some of them more recent than others. And another witness in the same case was permitted to testify that she lived in the same house with complaining witness; that about January 29th complaining witness was confined to her bed and that witness was called to aid her and found that she had fainted; that after she began to get well, witness found her washing stains from the tick

of her feather bed, and noticed stains upon her straw bed. Regarding the admissibility of this evidence the court said: “The objection that the facts occurred or appearances were observed a month after the alleged abortion does not render the evidence incompetent, though it may affect its weight. That they were not connected with the abortion we can not presume. We can not know that the result of the injury did not continue thus long.”

Effect of Proving an Alibi.—An element of defense sometimes available is that of an alibi, or the proving by the defendant that he was at another place than that at which the crime was committed at the time of the performance of the criminal act. The effect of such evidence is admirably shown in the case of Commonwealth vs. Snow.* Here the woman upon whom the abortion was alleged to have been performed testified positively that the operation was performed on May 29th; “that she knew it was upon that day; that she set it down in her diary upon the evening of that day or the next morning; that she had seen the memorandum upon her diary a number of times since then, the last time within a week prior to her testimony.” The woman’s sister, also the father of her child, each testified that May 29th was the day upon which the operation was performed. The former testified that her sister left home that day to have the operation performed, and the latter testified that he took the complaining witness to defendant upon that day, and that defendant performed an operation upon her with an instrument.

The defendant introduced evidence tending to show that upon May 19th, 29th, and 21st he was more than one hundred miles distant from the place where the operation was alleged to have been performed. The court, in instructing the jury upon the weight and effect they should give this conflict of evidence, instructed them that the exact day was not material; that “if the jury were satisfied that the witnesses for the government were in error as to the date stated by them, this was a proper matter to be considered upon the question of the degree of credit they were entitled to as to other matters; and if this, either alone or in connection with other evidence, caused the jury so far to doubt as to their truth and the reliability of their testimony in other matters that they were not satisfied beyond doubt that the defendant did perform the operation as alleged, then they should acquit the defendant.” The supreme court, in reviewing this case, said: “These rulings and instructions were right. If the alibi was satisfactorily proved, it was for the jury to say what effect it ought to have upon the testimony of the witnesses for the prosecution. It might discredit them altogether. If it did not have that effect, then it required an inference of some mistake on their part, either as to the person who performed the operation, or the true date of its performance. Their testimony was no more positive as to the date than it was as to the person; and they were at least quite as liable to have made a mistake as to the true date as they were in regard to the identity of the person. But in any respect it was entirely a question of fact for the jury, and was rightly left to them to decide.”

Illustrations.—Having generally reviewed the law relative to this class of cases, the chapter will be brought to a close with a brief examination of the evidence as

* People vs. Olmstead, 50 Mich., 431.

* Commonwealth vs. Snow, 116 Mass., 47.
shown in the reported cases upon which juries have based their verdicts in several instances.

The statute under which the case of State vs. Van Zile * was prosecuted provides that any person who with intent, etc., "either, first, prescribes, supplies, or administers to a woman, whether pregnant or not, or advises or causes a woman to take any medicine, drug, or substance; or, second, uses, or causes to be used, any instrument or other means, is guilty of abortion, and is punishable, etc." The evidence in this case shows that deceased, in company with a young man, went to defendant's office for the purpose of having deceased examined to determine whether or not she was pregnant. Defendant made an examination, announced that the girl was pregnant, and advised the young man, who, for the sake of convenience will be hereafter designated A., to marry her. For the examination defendant charged and received twenty-five dollars. Three days afterward, and on the eleventh day of November, defendant and A. met at a drug store, and, after a conversation in the corner, which was not heard by the clerk, defendant asked for pen and ink and paper, and wrote a prescription, which he gave to the drug clerk and said: "Put it up and give it to this young man." The prescription specified several drugs, which were required to be compounded and made into twenty capsules, one of which was to be taken after each meal. This compound was pronounced by a professor of materia medica to be an abortive mixture. On December 19th deceased had a miscarriage and sent for defendant. Upon his arrival the following conversation took place, so he testified: "The girl said, 'You don't remember me?' And I said, 'No; who are you?' And she said, 'I am the girl that A. had at your office.' And I says, 'What is your trouble?' and she said, 'I am all through my trouble.' 'When did it occur?' and she says, 'Last night.'" The girl became worse, and on the 24th of December the family physician was called in, who testified that the following conversation took place between himself and defendant. "He (defendant) told me that he had been called into the case, I think the Thursday previous, and that she had been getting rapidly worse, and was now in a very bad condition. He did not seem to understand what was the matter—what the trouble was." To the question, "Did he say so?" the family physician replied, "He said so." On the following day the girl died. Defendant went to the druggist and told him that the girl had died, and he thought if the druggist would lend him two hundred and fifty dollars he could pay the funeral expenses and in that way settle with and satisfy the mother. That night defendant fled from the city and remained absent for about three months.

The jury rendered a verdict of guilty. The general term of the supreme court, in reviewing the case, said: "A careful examination of the testimony leaves no doubt of the guilt of the defendant. While it is true that the evidence is circumstantial, and leaves the question of guilt to be determined by inferences drawn from established facts, yet the facts proved are not only entirely inconsistent with the innocence of the defendant, but they can be reconciled upon no theory except that of guilt." The case of Solander vs. People † is also one in which there was no direct evidence of the commission of the crime, and yet it is one in which the circumstances point so strongly to the guilt of the accused as to exclude all reasonable doubt as to her guilt. The principal witness was a man, who, for convenience, will be designated K. This witness testified that about three weeks before deceased's death he procured some medicine from Denver at her request for the purpose of producing an abortion, and that she took the medicine. That a little more than two weeks afterward, on Thursday, deceased went to see defendant, and that on the way home she told him that she had visited defendant for the purpose of employing her to procure an abortion, and that defendant had stated that it would be necessary to use an instrument and to procure medicine from St. Louis, and that she would charge thirty dollars for the services. K. further testified that on the following Saturday he returned with deceased, a distance of some eight miles, to defendant's office, and that defendant and deceased were alone about an hour; that defendant and K. then returned with deceased to her home, and that defendant remained there until Monday morning. Witness said that defendant told some powers and directors of the Missouri legislature, and that he gave deceased some of them, and that after taking each powder she fainted. Next day deceased died. Shortly before her death, however, the witness K. went for defendant and told her that deceased desired to see her. Witness testified to a conversation which then took place between him and defendant in which defendant disclosed knowledge of deceased's condition, and of the nature of her illness. That defendant stated that deceased had been taking medicine from Denver, and that if she should die that medicine would be the cause of her death; that, defendant said, would clear her. Witness testified that defendant inquired for the facts which had come from deceased, and requested him to take it away, as inquiry might be made for it. Witness testified that on the following day he returned with defendant to her home and that she then told him that she wanted to get a certain man, naming him, for her lawyer, and that she wanted to get two certain doctors, who were good friends of hers, to go over for the examination, and that she would be all right; and that if any one should ask witness what was the matter he should say that he did not know.

There was expert evidence offered to show that death was caused by an attempt to produce an abortion, and that an instrument was used for that purpose. Evidence was also adduced by the State that a boogie, broken into three pieces, was found upon the premises of the deceased, and that the injuries observed in the womb of deceased might have been produced by that instrument; also that the powders left with deceased bore a striking resemblance to gossypium, and that the effect of the drug was abortionary. A witness testified that when the boogie was found defendant disclaimed any knowledge of it, and said she did not know what instrument was used for procuring abortions; that she had never seen one. The coroner testified that at the request defendant told him that she supposed deceased was laboring under prolapagus uteri, and that she was treating deceased for that; but that he saw no indications in the body of deceased of prolapagus uteri. Defendant took the witness stand in her own behalf and denied having used any instrument, and also that she had advised it. She admitted having given powders, but denied that they were gossypium, and averred that they were not intended to produce abortion.

---

* People vs. Van Zile, 73 Hun, 534, 26 N. Y. Supp., 390.
† Solander vs. People, 2 Colo., 48.
Among other instructions, the court gave the jury the following: "Neither is it necessary that it should appear by the evidence that the prisoner, with her own hands, used any instrument upon the person of deceased, or that with her own hands prisoner administered to the deceased any drug or substance. If prisoner furnished any instrument to deceased or to any other person with intent that deceased or any other person should use such instrument for the purpose of procuring the miscarriage of deceased, she being then pregnant, or if prisoner provided any noxious drug or substance with intent that deceased, being then pregnant, should administer the drug or substance herself, or that any other person should administer it to her in order to produce the miscarriage of the deceased, prisoner thereby constituted the deceased, or the person to whom such instrument or drug was delivered or provided, her agent, and is accountable for all the acts of such person done in pursuance of the agency. And if such person, whether the deceased herself or any other, used such instrument upon the person of deceased, or administered such drug to deceased with the intent to produce the miscarriage of deceased, and by reason of such treatment the deceased came to her death, the prisoner is guilty as charged in the indictment, even though she was not present at the time of the use of the instrument or administration of the drug."

The jury returned a verdict of guilty, and the prisoner was sentenced to confinement in the penitentiary for a term of three years.

The supreme court, in reviewing the case, approved of the instruction above quoted, and also gave their opinion that the trial court had made no error in permitting the witness K. to testify to the conversation had between himself and deceased while returning from their first visit to defendant. The court, in discussing the question of admissibility of this conversation, affirms the correctness of the rule that a mere narrative of past events, not made in furtherance of the criminal design, is not evidence against one who was not present when it was uttered, and consequently cannot be repeated on the witness-stand. But the court continued: "Although the statement of deceased was made after the interview with prisoner, and was, in one sense, a history of a past event, it was during the pendency of the criminal enterprise, and closely attendant upon an act done to promote the illegal purpose. If the evidence was admissible upon the principle of res gestae, as I think it was, it would not have been proper to exclude it upon the ground that it was merely a narrative of past events."

The case of State vs. Clements * impresses one very forcibly as illustrating the danger attending the professional life of the medical man. Here the unfortunate combination of circumstances which entangled the defendant and brought disgrace and conviction upon him is one that is liable at any time to ruin an honest practitioner who has not the opportunity of protecting himself by the counsel and assistance of his reputable professional brothers, and it is one against which the honest physician can not take too great precaution.

The evidence in this case showed that the deceased was a young unmarried woman who had been stopping for some time at the hotel where she died; that on the morning of her death defendant locked her door and passed out of the hotel, and remarked to some one that she was sleeping quietly, and that he did not want her disturbed. A few hours afterward, at about nine o'clock A.M., defendant came back, and, upon going to deceased's room, called some one and stated that "Lena was dying." The defendant was immediately arrested and placed in charge of the constable. Upon leaving the hotel defendant told the constable that he had something to show him at his office. Upon arriving at the office he exhibited to the constable a fetus of which he said deceased had been delivered. Shortly before this, and at about the time deceased was first taken sick, the defendant exhibited in the drug store to the druggist a stout sharpened quill about six inches long, being bloody, and having the appearance of having been recently imbedded in living animal tissues, which he claimed to have taken from her room. He stated to the druggist: "I want you to examine this. I may need it for my protection. I am afraid this case will get me into a scrape yet. Some woman has been using this for a criminal purpose."

The post-mortem examination showed that there was some abrasion or scratching of the interior walls of the uterus, apparently caused by some rough instrument, but that the injuries were slight. There was no indication that deceased met her death by abortion produced by drugs.

The principal witness for the State was the colored cook of the hotel, who testified to finding deceased lying upon the floor of her room about the time she was taken ill, and, contrary to the objections of defendant's counsel and contrary to the law of evidence, was permitted to testify to the following conversation: "I asked her if the doctor had used instruments upon her. She said, 'Yes.' This statement, it will be seen, was not admissible as a dying declaration, nor was it a part of the res gestae, but was mere hearsay and inadmissible. It appeared also that defendant while attending deceased misrepresented the nature of her illness.

The evidence given by defendant upon his own behalf was that deceased applied to him on August 12th, nineteen days before her death, to perform an abortion upon her; that he refused absolutely to do it; that some ten or twelve days prior to her death deceased called upon him to treat her professionally for some derangement of the uterus; that he made an examination and found a sponge imbedded in the tissues in the mouth of the womb; that he used a metallic speculum and forceps, and removed the sponge; that he found the place occupied by the sponge lacerated, the sponge covered with pus, and very offensive; that he treated her for about six days, and dismissed the case. Defendant testified that he did not see deceased again until August 25th. when he was called by her; that she complained of nausea of the stomach, and pains in the abdomen, and upon being questioned denied having made any attempt at abortion; that symptoms rapidly disclosed themselves indicating labor pains; that he prescribed ant abortive treatment; that there were no other physicians in reach with whom to consult, and deceased had no means to employ medical assistance; that he continued such treatment; that deceased then informed him she had made an attempt to accomplish a miscarriage by inserting a quill into the uterus, and told him where the quill could be found, and which was shown to be the same quill before referred to; that thereafter, on the night of August 30th, deceased gave birth to a dead fetus; that for a considerable time prior to this de-

ceased was in such a condition that to have exposed the cause of her illness would have resulted in a nervous shock extremely dangerous to her life; that defendant removed the fetus and its appendages, and afterward surrendered them to the officer; that he administered opiates to deceased, placed her in bed for the purpose of securing repose, gave directions that she should not be disturbed, left the hotel, and went to his breakfast. That upon returning in about an hour afterward, he found her dead, uterine hemorrhage having set in during his absence, and caused her death.

The jury returned a verdict of guilty, and judgment was entered thereupon. The supreme court, however, upon reviewing the case, reversed the judgment and sent the case back for a new trial, because of errors committed by the court below. One of these errors was permitting the cook to testify to the conversation between himself and deceased which was above referred to.

The result of the second trial of the case is not known to the author.

Another case which shows to what extreme verdicts juries will sometimes allow themselves to be persuaded by the great zeal that often actuates prosecuting attorneys to secure a conviction, irrespective of the merits of the case, is that of Clarke vs. People.* Here the defendant was convicted of procuring an abortion upon the deceased, a young unmarried woman. There was much evidence taken, but very little of it reflects unfavorably upon the defendant. The substance of the evidence of the prosecution was that a miscarriage had taken place from the effects of which death ensued; that defendant was the sole attending physician at the time of the abortion and for some time prior and subsequent thereto; that defendant burned the fetus instead of burying it; and that in reply to a question propounded by the landlad of the house where deceased was stopping, defendant stated that the patient was suffering from inflammation of the bowels.

Defendant testified that deceased first sought his services on the twenty-fourth day of February, and that she was at that time suffering from "bearing-down pains"; that upon his next visit, which occurred next day, he cautioned her in reference to the danger she was incurring, and warned her against the effects of the course she had entered upon, advising her that she should reconcile herself to her condition and let the full time elapse before birth. At the end of this visit he was paid for his services and considered himself discharged from the case. Defendant testified that a few days later he was called again, and that deceased was threatened with a miscarriage; that it was too late to prescribe medicine to counteract the effect of the drugs she had previously taken, but that he did prescribe quiet and rest; that, finding this would not prevent the abortion, he did what he could to relieve the patient and save her life. It was shown that on the day before the patient's death defendant informed her she was not progressing so favorably as he had hoped, and that he desired a physician in consultation, and advised that her parents be notified. To both of these propositions deceased objected. Finding deceased worse next morning instead of better, defendant telegraphed her father and sent out for another physician, but, owing to delay, the latter arrived only shortly before her death. In explanation of the burning of the fetus, defendant testified that decomposition had set in, rendering an immedi-

* Clarke vs. People, 16 Colo., 511.
of acoline were inadequate to produce satisfactory anaesthesia. 3. Inspection of the cornea with a high-power lens failed to show any defects in the epithelium after its use. 4. Acoline has no effect upon accommodation. 5. It has no effect upon the size of the pupil. 6. It does not increase intracocular tension. 7. Several experiments showed that the Staphylococcus pyogenes albus did not grow in agar which contained acoline in the proportion used in the clinic, and furthermore, that exposure of this organism to the action of acoline for twenty-four hours was followed by its death. This would look as though acoline were not only an inhibitor of the growth of the Staphylococcus albus, but that it also killed this organism after a certain length of time. It is, of course, evident that conclusions drawn from this limited experience with acoline may have to undergo more or less modification with further trial.

The Uses of Rectal Irrigation in Gynaecology.—Dr. C. R. Hyde (American Gynaecological and Obstetrical Journal; Canada Louise, October) epitomizes a paper on Rectal Irrigation in Gynaecology: Rectal irrigation has been found to have a distinct value: 1. In leucorrhoea. 2. As a substitute for vaginal douching in young girls. 3. In acute and chronic ovarian and tubal lesions, with the possible exception of pyosalpinx. 4. In intestinal paralysis following sepsis. 5. After major pelvic operations to relieve any abdominal discomfort or tympanites. 6. In intestinal colic. In constipation its value is doubtful. The author says that rectal irrigation commends itself to gynaecologists for thoughtful and unprejudiced consideration, as having seldom failed to meet the test on fair trial. For the irrigation either a rubber, aluminum, or glass tube is used, and at least two gallons, preferably from six to eight, of saline solution at a temperature of from 110° F. to 115° F., are employed. The advantages of this method over the vaginal douche lie in the fact that a much greater amount of fluid may be used, and that it comes in contact with a much greater vascular surface.

Psilosis, or Aphthae Tropicæ.—Psilosis, or tropical "sprue," is a disease of tropical climates in the Far East with which some of our physicians practising in our newly acquired Eastern possessions may become acquainted. Dr. George Thin, president of the Section of Tropical Diseases of the British Medical Association (Journal of Tropical Medicine, September), read a paper on this disease at the last meeting of the association. He said that the disease was characterized by certain symptoms which were never absent. Irregular and abnormal motions were always present. There was, first, diarrhea, varying much in severity, frequency, and persistence. Secondly, there were always symptoms of disordered digestion. Thirdly, there was progressive emaciation. Dr. Thin distinguished two types of the disease: One, common in the eastern archipelago, and one more common in India. In the first, mouth, tongue, and throat symptoms were early prominent, and the most pronounced and disagreeable symptoms. In the second, copious watery stools were the prominent symptoms, those previously mentioned not manifesting themselves till later in the disease. The pathology of the disease was indefinite, but there was a special connective-tissue development, a true sclerosis of the submucous, which was specially characteristic in the ileum. The aetiology was unknown. The author considered the disease specific in character, and its best soil for development in the ileum. As to treatment, Dr. Thin said that it might be starved out by limiting the patient's diet, and it appeared not to grow if the food consisted exclusively of milk. An exclusive diet of meat juice seemed in some cases to lead to its annihilation, possibly due to the fact that a strict meat-juice diet, to the extent to which it was practicable, was largely a starvation diet. Milk was not the only nutrient in which it did not thrive. He had previously referred to cases in which strawberries were not only well borne, but were curative in this disease, and possibly other fruits might have similar qualities.

The author then described a remarkable case: The patient was a lady under the care of Dr. Playfair (Bronley), with whom she saw her. Her anemia, wasting, and debility were extreme, and the prognosis he considered bad. She had had the disease for a period of years. Among other treatments, milk treatment appeared to have had a thorough trial, and apparently little new was left to suggest. That little consisted in keeping the room night and day at a temperature of 64° F., and in never allowing the patient to be removed from under the bedclothes, on the theory that the skin should be kept constantly warm to diminish congestion of the mucous membrane. On this treatment the diarrhoea ceased, but the quantity of milk taken was too small to render recovery possible. After six weeks of this very limited milk diet, at her own instance she began to take strawberries, steadily increasing the quantity. With an increasing amount of strawberries she was able to take more milk, until she ended in taking a large quantity of milk and several pounds of strawberries a day. She made an excellent recovery, became healthy and strong, and could now eat ordinary food without bad consequences. Dr. Thin's theory of this and similar cases was that, whatever the cause of the disease might be, it did not live on the strawberry juice, and that a diet of strawberries and milk starved it out.

The Detection of the Morphine Habit.—The Atlanta Journal-Record of Medicine for October cites from the Medical and Surgical Bulletin of uncertain date the following method of detecting morphine in the urine of suspected subjects of the morphine habit: "Collect about twenty ounces of urine from the suspected individual. If it has not an acid reaction, acidulate with dilute hydrochloric acid until blue litmus is reddened by it. Concentrate to about three ounces, and let it stand in a cool place for twelve hours, then filter. To the filtrate add sufficient sodium carbonate to render it alkaline; let it stand for twelve hours, filter and collect the precipitate, and wash this with distilled water made slightly alkaline with sodium carbonate, and dry. Digest the dried precipitate with pure alcohol at a gentle heat, and filter; evaporate the filtrate to dryness, dissolve the residue with dilute sulphuric acid, and test for morphine by the iodic-acid test, or other well-known tests. By this method morphine can be obtained, says the author (sic), from persons taking but very minute amounts of the drug."

Favus of the Penis.—Glück (Archiv für Dermatologie und Syphilis, Band xliv, Heft 3; University Medical Magazine, October) reports the following unusual case: Upon the side of the penis of a man, thirty-three years old, and upon the upper portion of the external surface of the foreskin, were several lentil-to bean-sized, round and oval, dry, sulphur-yellow crusts with elevated edges and depressed centres. Upon the inner
surface of the foreskin and the corresponding part of the sulus and corona were similar crusts, which extended along the side of the glans forward to the meatus, which they surrounded. No trace of the disease was to be found elsewhere upon the body. Upon microscopical examination the crusts were found to present an almost pure culture of the aschiorfungus. The author regards this case as a new proof of the correctness of Pick's view, that favus is not confined to parts provided with hair.

Upon this the abstractor comments as follows: Hardy has quoted Bazin as having seen a case of favus of the glans penis. In this case, however, with the aid of a lens, a minute hair was seen piercing the centre of the favus crust.

Unilateral Diffuse Hypertrophy of the Breast.—Dr. Frank E. Bunts (Cleveland Medical Gazette, September) reports the case of a girl, aged nineteen years, in whom the left breast was enormously hypertrophied, the right being, on the contrary, somewhat atrophied. The enlargement commenced at the age of fifteen years.

Dr. Bunts removed the breast, using the portion of integument below and including the nipple for the flap, and removing the entire breast and integument above the nipple together. When sutured this brought the nipple slightly higher than on the opposite side, but the flap, being somewhat redundant, contracted, and two years subsequently to the operation the nipple appeared in about the right place and there was very little disfigurement. The author considers this case as one of considerable rarity because of its diffuse instead of circumscribed hypertrophy, its being unilateral instead of bilateral, and because, while the growth developed during the period of active development of the generative organs, there was never any disturbance or irregularity at any time traceable to those organs which might have accounted for the unusual development of the breast.

Disurbances of Sensibility in Parkinson's Disease.

M. A. Palmieri and S. Arnaud (Clinica medica italiana, 1899, No. 6; Settimana medica, September 9th), notwithstanding the common denial by pathologists, including Parkinson himself, of the existence of objective sensory disturbances in subjects of Parkinson's disease, instituted observations in seven cases with the result of demonstrating that there were always disturbances of the sense of pain, but rarely of the other forms of sensibility, tactile, thermal, etc. He arrived at the following conclusions: 1. In the subjects of Parkinson's disease there is nearly constantly a diminished pain sensibility, at times very marked in the region affected by clonic spasms. 2. The hypalgesia is at times diffused, at times in detached areas, and is generally most marked at the extremities of the limbs. 3. Perhaps in the very first stages of the lesion there is hyperalgesia, which gives place to hypalgesia, and the latter grows more and more decided as the disease advances.

Results of the Open-air Treatment of Phthisis.—Dr. A. W. Philip (West London Medical Journal, October), writing in a symposium on British Sanatoria for the Open-air Treatment of Tuberculosis, sums up the results as follows:

(a) In the first place, it is right to emphasize that during prolonged experience of this treatment I have not witnessed one untoward incident resulting therefrom. During the years which have elapsed since the hospital was opened there has not been a single day on which some of the patients have not been outside, and on most days almost all have been able to be out for a time. Rain and snow have not been allowed to form a contraindication. In such weather the patients are suitably shod and mantled, the shoes and mackintoshes being put on and thrown off in an outer hall.

(b) A remarkable change of type of disease occurs speedily. Within three or four days the patient's color begins to manifest a healthier aspect. His appetite rapidly picks up, so that patients whose chief complaint was anorexia may within ten days or so eat voraciously.

Night sweats disappear almost at once. Again and again I have admitted patients either from their own homes or from other hospitals who required to have their clothing changed several times throughout the night, and within a week's time those patients have ceased to manifest this distressing symptom, their night rest being simultaneously benefited. So uncommon is this symptom that, while I was anxious to accord to the requests of some patients that he may have the opportunity of conducting some observations thereon, he had to go elsewhere in order to obtain sufficient material. Similarly, the temperature in most cases, which may have been both irregular and high previous to admission, tends gradually to assume the normal, or rather the slightly subnormal, which is the rule in many cases of latent tuberculosis. In like manner the cough quickly lessens, and finally disappears. It has been frequently remarked to me by visitors going round the wards how seldom the patients coughed. The body weight, too, and general conditions show corresponding improvement. An increase of fourteen to sixteen pounds has not been an uncommon incident during the comparatively short stay which a hospital with limited accommodation for poor patients permits.

(c) The educative value of such residence can not be overestimated. The patients learn unconsciously how to treat themselves. They realize how practically true it is that open air, day and night, and sunlight, are their best friends, and that attention to hygienic measures can be their salvation. They thus become on their discharge from the hospital apostles of the new faith, and one frequently hears of the results of their teaching in their own homes.

(d) In so chronic and treacherous a disease it is not wise to speak confidently of cures effected. The proportion of patients, however, who have left the hospital and maintained for years continuously good health, and been able to resume regular work, perhaps with a change of employment, is a large one. The list includes cases where both lungs and larynx were involved on admission. On the other hand, disappointments are frequent. Some of the most promising cases have returned on our hands or have gradually fallen back elsewhere. The proportion of these cases is larger than it should be, from causes over which we have meantime no control. In the first place, our patients are chiefly in poor circumstances, and are compelled too rapidly to resume the conditions of life which induced the disease. And secondly, the resources of the institution are so limited, and the demands so enormous, that the patient's stay in hospital has often to be curtailed when it ought to be prolonged.

(e) The course of treatment is a pleasant one. There are none of the drawbacks which have sometimes been portrayed in relation to hospitals for consumptive patients. Far from being a gloomy place, our hos-
PITH OF CURRENT LITERATURE.

Dr. J. J. Charles (British Medical Journal, September 30th), professor of anatomy and physiology, Queen's College, Cork, says that a difference of opinion exists as to the function of the rectum. Some, as Stewart, maintain that the rectum is empty and at rest except during defecation, when the entrance of faeces excites the nervous process, and causes in consciousness the desire to defecate. The rectum, however, may be found full of faeces—sometimes even to the anus—in the dissecting room; and surgeons, such as Mr. Treves and Mr. Allingham, have informed him that they frequently find it in this distended state during life. Besides, the existence and arrangement of Houston's valves in the rectum and the strength of the internal sphincter indicate that the rectum—at least its suprasphincteric portion—serves as a reservoir, and not merely as a passage for the faeces. Accepting this view, the accumulation of faeces—sometimes, no doubt, of a more irritating nature than at others—starts the reflex action, which, as a rule, is aided by voluntary action. The fact that defecation can take place when the lower part of the spinal cord has been removed, as in Goltz's and Ewald's experiments, would lead us to believe that the nervous mechanism may to a certain extent be local. It has been affirmed that defecation, like the daily variations in the number of respirations and in the temperature of the body, may be a process which tends to take place in a cycle. The effect of habit in causing defecation to occur regularly at the same time supports this idea.

Perforation of the Stomach in an Infant Seven Weeks Old.—Dr. T. M. Rotch (American Journal of the Medical Sciences, October) reports the case of a male infant, aged seven weeks, admitted to the Infants' Hospital, February 2, 1899. The infant had been well until four days previously, when his abdomen became suddenly much distended and he appeared to suffer considerable pain. After the first twenty-four hours the bowels had moved regularly and the pain had lessened. Vomiting had begun about eight hours before entering the hospital.

The infant was well developed and fairly nourished. The facial expression was rather drawn, the eyes dull, and the abdomen much distended and tympanitic, excepting that there were very slight areas of dulness in both inguinal regions. A few coils of distended intestine could be detected. The pulse was 165, the temperature 101° F., and the respirations 35. The diagnosis of peritonitis was made, and it was decided to operate at once. Ether was given, and an incision four inches long was made in the median line, and about two drachms of slightly flaky serum exuded. The vessels of the much-distended small intestine, and especially of the mesentery, were found to be very much injected. A few flakes of lymph were found adhering to the intestines. The intestine was thoroughly examined, practically through its whole extent, without any cause for the peritonitis being discovered. The abdominal cavity was irrigated and the wound closed. Three days later the infant died.

At the autopsy, eighteen hours after death, the body was that of a well-developed infant; rigor mortis was present. There was an incised wound about six centimetres long in the median line of the abdomen just below the umbilicus. This was partly closed at the ends by interrupted sutures, while from the middle projected a wick of gauze. This reached well down to the root of the mesentery, and was surrounded by coils of intestine, which were glued to the abdominal wall and to each other. There was no free fluid in the pocket drained by the wick. The adhesions between the coils of intestine could be easily separated, and lying between them was a little opaque, turbid serum in which were occasional flakes of lymph. The head was not opened.

The lungs were of normal color, well retracted, with a few dark, slightly depressed areas. The pleural surface was smooth and the cavities normal. The heart was normal and weighed sixty-five grammes.

The stomach was quite extensively adherent to the diaphragm along its anterior surface, and on carefully separating the fibrous adhesions one point was noticed where the exudation was a little thicker and more adherent. In fact, it was evident that a collection of pus, apparently coming from the wall of the stomach, was a minute thread about two or three millimetres in length. There was also here a little more injection than elsewhere.

On opening the stomach it was found to be generally normal, with the exception of a minute loss of substance surrounded by a reddened zone opposite the place of greatest exudation on the outside. This portion of the wall of the stomach was cut out, and after hardening in Zenker's fluid was mounted in paraffin and a series of sections cut. As the result of the studies of these it appeared that there was an oblique passage from within outward through the entire thickness of the wall, and in it lay a foreign body made up of a bundle of very small, irregularly rounded, structureless fibres, staining intensely with aniline dyes, but not with haematoxylin.

The edges of the mucosa were slightly rounded over from within outward, as if the original lesion had been in that direction. The cavity in the middle of the coat was partly filled with leucocytes and round cells surrounding the fibres, but not infiltrating among them, and nowhere did the foreign body project into the interior of the stomach.

After staining by Gram's method, large numbers of small rod and spherical bacteria were found on the peritoneal surface close to the thread. No cultures were taken at the autopsy, on account of the lapse of time after death. The liver was normal in appearance and weighed a hundred and sixty-five grammes. The kidneys were pale, and together weighed thirty-five grammes. The spleen was dark red and weighed fifteen grammes. The pancreas, adrenals, and the genital organs presented nothing remarkable.

The chief interest in the case centres in the perforation and its cause. That the general peritonitis had started from this point there was little doubt, as the evidences of the inflammation were most extensive here and the exudation was thicker and firmer. It is highly improbable that this could have been anything introduced at the time of the operation, for to have produced the lesions would have required several days, as shown by the thinned and somewhat everted mucosa. How the perforation took place from the inside is also hard to understand if this foreign body is nothing but a bit of silk thread, as its structure would indicate. It is suggested that possibly a threaded needle was swallowed, and had perforated, leaving a bit of silk behind,
and the needle was overlooked among the coils of intestines. It certainly was not thought of at the time of the autopsy, and no especial search was made for it. Another suggestion is that it was a case of follicular ulceration, and the bit of thread had worked its way into that. But the loss of substance in the mucosa is rather less in extent than deeper in, and there is no evidence of any inflammation in the neighborhood that would warrant the assumption of such a process. We are left, therefore, with the simple fact that the local lesions are all in the immediate neighborhood of the foreign body, and that the perforation and the secondary fatal peritonitis must be referred to it.

**Adherence of Membrane to the Cervix an Important Cause of Tardy Dilatation of the Cervix.**—Löhlein (Centralblatt für Gynäkologie, No. 19: International Medical Magazine, September) records a number of cases in which this condition has been the cause of delayed first stage of labor. This adherence is due to a cervical or corporeal endometritis. He advises incising the finger and detaching the membranes from the wall of the cervix and, if necessary, rupturing them. The adherence of the lower pole of the ovum to the cervix delays the unfolding of the cervix and prevents the descent of the bag of waters, and the consequent dilatation of the internal os.

**Further Report on Antiphthisic Serum T. R. (Fisch) in Tuberculosis.**—Dr. Mansfield Holmes (Journal of the American Medical Association, October 7th) supplements his recent reports on Serum Therapy in Tuberculosis, published in the New York Medical Journal, March 25th to April 8th, and in the Journal of the American Medical Association for April 1st, with a further paper presented to the meeting of the American Medical Association at Columbus. Dr. Holmes, for convenience of description, arranges the cases into two groups: 1. Those in the earliest incipient stage which had not advanced to the stage of expectoration in which bacilli could be found. 2. Those in the stage of expectoration with bacilli present.

There were nineteen cases belonging to the first class. These cases gave the usual symptoms belonging to the incipient stage. The majority of them gave a strong tuberculous family history and had been sent to Colorado by their physicians. The tuberculin test was made in thirteen members of this class, followed by reactions. The remaining six cases had symptoms equally pronounced, but were not subjected to the tuberculin test. Without a single exception each case belonging to the first group made rapid improvement under the serum treatment. At the close of the treatment they were again subjected to the “O. T.” test and failed to react. Furthermore, there had been but one patient of this group that relapsed after improving under the serum, and he had remained in good health for nine months before relapsing. Treatment was then resumed and continued for five months, during which time all symptoms disappeared. At the expiration of this time the tuberculin test was given without reaction. The patient was now in excellent health.

The second class embraced thirty-one cases. Of this number, eleven were in the incipient stage and twenty were advanced cases. Of the eleven belonging to the early-stage class, four were cured, the bacilli disappearing completely. Five cases made distinct improvement, but the serum was discontinued too soon. Two cases were improving and the treatment was being continued. Of the twenty advanced cases, four made distinct improvement. Seven improved slightly, but subsequently failed. Three made no improvement, and six died. He would state, however, that one of the deaths was due to pneumonia, the result of exposure, involving the unaffected lung, and also that many of the cases included were under the serum treatment but a short time. Experience had proved that the best effects might be expected only after an extended use of the serum. In many of the advanced cases the serum was discontinued as soon as he became convinced that nothing could be expected from it.

Until recently he had made no effort to select cases, as he wished to ascertain from actual experience the advantages to be expected from the treatment in the various stages of the disease. It was a well-known fact that the majority of persons in the early stage of the disease were not easy to convince of the necessity of supplementing the climate of Colorado with treatment. But when patients tested climate and found it insufficient to bring about a cure, they were ready to accept almost any treatment that was recommended to them. Hence, there was always an abundance of those patients in the last stage of the disease willing to try almost any serum treatment. He regretted to state that in almost all advanced cases the benefit had been slight. It had possibly prolonged life. But in the well-advanced cases he doubted if the serum was able to even prolong life to any great extent.

Three of the foregoing cases were of long standing and were in the last stage of the disease, with extensive involvement of tissues, when beginning the serum. This was early in his experience with serum, and he abandoned its use as a last resort. Each of these patients continued its daily use for five months. At the time of beginning the serum he believed they had but a few weeks to live. Each patient made slow but distinct progress. It might also be of interest to note that from twelve to fifteen months had elapsed since stopping the treatment, and these three patients were alive to-day. Two of this number were now in moderately fair health—the disease having assumed a chronic form—but were by no means cured. The third patient relapsed about nine months after stopping the treatment, the result of his own imprudence, and was now in a very low condition. He mentioned these three cases, not for the purpose of showing that the serum was capable of curing cases after they reached such an advanced stage of the disease, but to show that the disease might be temporarily checked and the lives of such persons indefinitely prolonged.

Dr. Holmes says that: 1. In well-advanced cases the serum invariably causes an elevation of temperature, which usually occurs from three to six hours after its administration. The temperature at such times frequently reaches 106° F. to 104° F., but remains high only for a short period. At first he was in doubt as to the cause of this marked elevation of temperature. It was a question as to whether it was due to the serum or the disease. He therefore discontinued the use of the serum for a short period with a few patients who experienced the high temperature following the doses, and in each case the temperature dropped to normal or close to normal. He is unable to account for this fever in advanced cases unless it is due to the cumulative action of the serum, with a greater susceptibility of the advanced cases. 2. We also experience, from a prolonged use of the serum, a more or less extensive infiltration of the
areas used for injections. These areas do not become tender or painful, but remain more or less infiltrated. In such cases the skin is not readily elevated from the body; the subcutaneous cellular tissues, being the seat of the infiltration, bind the skin more closely to the deeper tissues of the body. 3. Long and persistent use of the serum produces depressing effects, which are best relieved by a short interval of rest. The treatment should, however, be resumed again with small doses. 4. Sooner or later he has found that the lymphatic glands become tender and enlarged from the use of the serum. In some cases this is experienced within three or four days. In the majority of cases, however, it occurs at the end of a week or ten days. In a few cases this is not experienced until much later, or until the dose is increased.

In cases experiencing good effects of the serum, there is invariably an increase in the percentage of young lymphocytes of the blood. On the other hand, in rapidly declining tuberculous cases, he has observed a progressive decrease in the percentage of young lymphocytes. He has found no exception to these rules.

Addison's Disease in a Young Girl.—M. Haushalter (Gazette hebdomadaire de médecine et de chirurgie, September 14th) recently exhibited to the Medical Society of Nancy a young girl, ten years of age, affected with Addison's disease. The affection was of about two months' standing and was marked by lassitude, melancholy, and an abnormal pigmentation of the face, neck, and back.

---

**Book Notices.**

Those of us who have the good fortune to possess the unabridged edition of this excellent work (two volumes) can readily appreciate the great value of the present condensed and revised treatise, presenting as it does all the essential features of the larger work, with, moreover, the further advantages of a recent revision and the addition of a complete series of illustrations, as well as a number of beautifully executed plates, some of them in colors, which have been expressly prepared for this volume.

We are very much pleased to note the distinction made by the editor in the opening chapter between hemiplegia due to extrinsic disturbances, such, for instance, as injury, and inflammation (infection) due to intrinsic factors—namely, micro-organisms. Their distinction is necessary before proper treatment can be adopted. Especially commendable is the chapter on the surgical pathology of the blood, which in the past has found but little space in the average surgical text-book. The determination of the percentage of hemoglobin is of special value; as the author says, "a prognostic signification often attaches to the accurate estimation of the hemoglobin at intervals after removal of malignant tumors."

The book has been conveniently divided into six parts, and they cover the subjects of surgical pathology, surgical diseases, surgical principles and methods and minor surgical procedure, injury and repair, surgical affections of the tissue system, and special, or regional, surgery. The present work maintains the high standard already established by the former edition, and requires no further praise or comment.

Practical Anatomy: including a Special Section on the Fundamental Principles of Anatomy. Edited by W. T. Eckley, M. D., Professor of Anatomy in the College of Physicians and Surgeons, University of Illinois, etc., and Mrs. Cornine Bufford Eckley, Instructor in Anatomy in the Northwestern University Dental School, etc. With Three Hundred and Forty-seven Illustrations, many of which are in Colors. Philadelphia: P. Blakiston’s Sons & Co., 1899. Pp. xi—9 to 485. [Price, $3.50.]

This work is not intended to cover the whole field of the vast subject of anatomy, but to present to the student and practitioner the general anatomy of the body only, leaving the special regions, such as the ear and eye, to works of greater scope. The book, therefore, will fill the particular field of a dissecting-room guide. The student will find it of special value, and the frequent review quizzes which have been made a special feature in the work will materially aid him in fixing firmly in his mind the ground already traversed. Again, the introductory chapter, on the rules, principles, and generalizations which underlie the science of anatomy, will be found a great help in properly understanding the formation and meaning of anatomical terms, together with the rationale of naming muscles.

The authors, as they state in their preface, have drawn freely from Morris's Human Anatomy, not only for the material of their text, but for a number of illustrations as well. Of the illustrations, sixty-six are original drawings, mostly diagrammatic. The work combines the usefulness of both text-book and quiz compend, and will therefore directly appeal to the student, whose path will be made easier by the combined efforts of the authors.

The author has prepared this manual of pediatrics especially for the use of students, and has devoted his efforts principally to infant physiology and artificial feeding. The pathology and treatment, however, have not been overlooked, but all the essential information concerning them has been given. For fuller treatises on the subjects the reader is referred to larger works.

The book opens with a description of the normal infant at birth, and describes the varying conditions of its later development. Diseases of childhood follow, and
these subjects are not only arranged in a systematic form, but show, besides, careful selection of material. Each chapter is lucidly yet succinctly written, thus greatly adding to the attractions of the book.

The writer concludes with a chapter on infectious diseases, including the exanthemata. In this we find most of the colored plates, which include a very accurate drawing of Koplik’s spots, and one of a similar variety seen in aphthous stomatitis, with which they are sometimes confounded.

The printer’s and bookmaker’s work is excellent, and we have in this volume an attractive addition to this series of pocket text-books.

BOOKS, ETC., RECEIVED.

The Logic of Figures, or Comparative Results of Homceopathic and Other Treatment. Edited by Thomas Lindsley Bradford, M. D. Philadelphia: Boericke & Tafel, 1900. Pp. xii–11 to 212.

The Twenty-sixth Regular Report of the Medical Staff of St. Francis’s Hospital. For the Year 1898. The Record of Four Years (1895–99) in an Exclusively Electro-therapeutic Clinic. Report of the New York Electro-therapeutic Clinic and Laboratory. By Margaret A. Cleaves, M. D., of New York.

The Treatment of Nasal Stenosis due to Defective Septa, and the Treatment of Hay Fever. By Beaman Douglass, M. D. [Reprinted from the Laryngoscope.]

Are the Dangers of the Menopause Natural or Acquired? A Physiological Study. By Anna M. Galbraith, M. D. [Reprinted from the American Gynaecological and Obstetrical Journal.]

Epiphora, or the Watery Eye: its Complications, Aetiology, and Management. By J. H. Woodward, M. D. [Reprinted from the Medical Record.]

The Pauper Inebriate—His Legal Status, Care, and Control. By L. D. Mason, M. D., of Brooklyn. [Reprinted from the Quarterly Journal of Inebriety.]

Accessory Thyroid Tumors at the Base of the Tongue. By Jacob E. Schadle, M. D., of St. Paul. [Reprinted from the Journal of the American Medical Association.]

Second Report of the Committee of Inspection appointed by the Executive Committee of the Post-graduate Medical School to review the Experiments of Dr. John F. Russell in the Treatment of Pulmonary Tuberculosis at the Post-Graduate Hospital. [Reprinted from the Post-Graduate.]

A Case of Polymorphism. By Henry A. Robbins, M. D., of Washington. [Reprinted from the Maryland Medical Journal.]

The Mercurial Vapor Bath. By Henry A. Robbins, M. D. [Reprinted from the Maryland Medical Journal.]

Die Radiotherapie der Hautkrankheiten. Von Dr. Leopold Freund, in Wien. [Separatabdruck aus der Wiener klinische Wochenschrift.]

Purulent Encephalitis and Cerebral Abscess in the Newborn due to Infection through the Umbilicus. By Guy Hinsdale, M. D. [Reprinted from the American Journal of the Medical Sciences.]

Miscellany.

The “Cleavage” between Doctors and the World at Large.—The British Medical Journal for October 14th has the following admirable remarks in an editorial on Medical Education:

“The Spectator, in an article on introductory addresses, expresses regret at their tone: ‘All of them are full of thought and penetrated with philanthropic feeling, but we could wish to have seen more stress laid on the advantage of liberal culture to the whole profession.’ While it is admitted that the members of the medical profession have shared in the general advance of education, it is asserted that ‘the rank and file still need a caution that power of thought is as valuable to a physician as experience, and that if he has to ‘mix his medicine with brains’ the brains must be cultivated as well as the faculty of perception. The tendency is still toward a concentration of thought upon science, and especially science as applied to the cure of disease, which makes of doctors more of a caste than the members of any other profession, except the navy.”
“It may be a surprise to many of us to be told that medicine makes so distinct a mark on a man; but it is a good thing sometimes to see ourselves as others see us, and in this case the eyes are certainly not unfriendly. But the writer goes further, and asserts that there is a certain latent cleavage between doctors and other educated men which is most injurious to both—to the doctor because it thins alike his interests and his knowledge, to the others because they fail in the sympathy with medicine, which if it existed would double the doctors’ beneficial influence.’ In support of this assertion we are asked whether, when any epidemic is present, we do not find the difficulty of driving our ideas into the heads even of the educated almost maddening. There ought to be no such difficulty, and there would not be, we are told, were it not for ‘a certain difference in ways of thinking, produced by a difference of culture, which we contend ought not to exist.’ We have here the other side of the shield to that shown to us by Sir W. Gairdner in his address at Mason College, an address which we cannot help suspecting the writer in the Spectator had not read.

“In the particular instance quoted it is open to us to retort that the difficulty is so great, not because the doctor has not learned the humanities, but because the other has not received even so much education in secondary influence as to be able to understand its point of view. The retort will not convince an opponent, but the contention finds support in the facts, as we believe them to be, first, that the cleavage referred to is less to-day than it was ten years ago, very much less than a generation ago; and secondly, that the difficulty is slight when the persons to be convinced are members of another scientific profession—chemists, for instance, or engineers.

“We can not admit that the medical profession is asking that aspirants for admission to it should have a less broad education than others, least of all on one of the grounds assigned, that ‘the mind predisposed to scientific inquiry is not, as a rule, interested in the humanities, and therefore wastes time in studying them.’ If such a ground has ever been taken, it certainly is not taken at the present day. It is true that we have had to let Greek go, mainly for the reason that so little was really learned either of Greek language or literature that it seemed wiser to give that little up in the hope of getting more Latin and modern languages. Whether the failure with Greek was due to want of time or to bad teaching who shall say? At any rate, the medical schools have to take the product of our secondary schools, where a love of the humanities ought to be instilled. We venture to say that the cause of the cleavage which our contemporary perceives dates from an earlier period than that at which university or technical teaching begins. In the case of the majority of boys intended for the medical profession the necessity for economy is a main consideration. A school must be chosen not because it is the best, but because it is within the parents’ means. Therefore it is that we have ventured frequently to express in these pages the belief that the organization of secondary education which the government has taken in hand is a matter which very nearly concerns the medical profession.

“That others perceive a line of cleavage between the medical and other professions is, even though we may not agree with them that the cleavage is altogether due to a falling away on our side, a serious matter for our consideration, for it must tend to alienate the sympathies of those who ought to be our strongest allies, and so intensify the evil influences which at the present day are working to diminish the influence and the material rewards of the medical life.”

How a Doctor Got a Clock.—The Sun recently reproduced the following from the Philadelphia Record:

“In the hallway of a Philadelphia doctor’s house stands a fine example of a grandfather’s clock, the possession of which the medical man owes entirely to a pinch of snuff. Some years ago the doctor in question set his heart upon such a timepiece and devoted two of his vacations to clock hunting. He visited many New England farmhouses without success, as old furniture is not been pretty well gathered up by the dealers ‘down East,’ and then carried his quest into Delaware and Maryland, where he found many old clocks, but none of them for sale.

“He was about to return home disconsolate, when he was called into consultation over a patient dying of quinsy. The resources of medicine had been exhausted, when the Quaker City doctor thought himself of an old snuffbox he had picked up during his wanderings, in which still lingered a modicum of snuff, pungent as of yore. With this powdered tobacco the doctor asailed the nostrils of the sick man, who, sneezing violently, broke the abscess in his throat that was choking him to death. Stimulants were administered and the sick man recovered.

“The Philadelphia doctor left the place the morning after this remarkable operation, but he had not been home a week before the grateful Marylander sent him a grandfather’s clock, accompanied by a card upon which was written: ‘This clock, which struck the hour of my birth, would have also marked the hour of my death if your skill and knowledge had not stayed the hand of the destroyer.’”

The First International Congress of Professional Medicine and Medical Deontology will be held in Paris from the 23d to the 28th of August, 1900, as a feature of the universal exposition of that year. The organization committee, of which M. L. Lereboullet is president and M. Jules Glover secretary-general, are issuing circulars of information and inquiry returnable before the 1st of July at the latest. The committee for the United States consists of Dr. G. H. Simmons, of Chicago, and Dr. H. S. Fuller, of Hartford; that for Canada, of Dr. J. G. Adami and Dr. Brodeur, of Montreal, and Dr. Persilien-Lachapelle, of Quebec.

The Treatment of the Abdominal Viscera through the Colon.—At the recent Chicago meeting of the Mississippi Valley Medical Association a paper entitled Further Observations on the Treatment of the Abdominal Viscera through the Colon was read by Dr. Fenton B. Turek, of Chicago, who first remarked that in a previous communication he had shown that small quantities of hot water at 131° F., introduced into the rectum, produced a marked effect on the heart and general circulation and especially on the abdominal organs. From these results it was evident, he said, that water of that temperature, introduced into the colon, had a greatly beneficial effect upon the abdominal viscera. Air, hot or cold, forced through a double tube into the colon and allowed to escape, also not only acted as a powerful stimulant to the abdominal viscera, but also set up a species of pneumatic gymnastics of the colon. In the introduction of hot water into the colon, the following procedure was adopted: The patient was placed
in the dorsal posture upon a table specially devised for the purpose, which was so adjusted that the hips could be raised or lowered to any desired angle without discomfort. The solution employed was usually a normal salt solution when the therapeutic effects of heat and cold were desired. For other purposes mild antiseptic and medicated solutions might be employed. A soft-rubber tube, either single or double, with end and side openings, was introduced into the rectum as far as the sigmoid flexure. At first from six to eight ounces of water at a temperature of 132° F. was introduced. This was allowed to return through a tube into a conveniently placed receptacle, and the procedure was repeated. Every time the water was introduced its temperature was gradually raised until it reached 131° F.; in all from three to six quarts were needed. The patient was then allowed to evacuate the bowels. After that he received similar short treatment with water cooled to 35° or 40° F. The amount of water introduced and withdrawn and the duration of the treatment depended upon the character of the case.

For continuous irrigation the author's double-recurrent tube, or needle douche, had answered the purpose best in the hands of such men as Herschell, Treves, Gillespie, and others. By continuous irrigation a somewhat different action was obtainable. It was indicated in impaction, in acute gastro-enteritis, and during the early stages of appendicular inflammation. The mucous membrane of the colon, like that of the throat, said Dr. Tureck, seemed to be insensitive to comparatively high temperatures. The sensations within the colon, as to heat or cold, are not very definite. This might in part be due to the fact that the colon's sensibility had been so specialized for faecal pressure as to cause it to lose its heat and cold reaction. That the treatment through the colon not only influenced the general circulation, but also stimulated the nerve actions of the abdominal viscera, and even the cerebral and spinal blood pressure, had long been known. The principle on which stimulant enemata had been employed in opium coma and allied conditions was a significant evidence of this. The anogenital centre was notoriously the last to be affected in coma. Numerous instances had been reported in which death from opium coma and anaesthesia had been prevented by its stimulation. Furthermore, stimulation of the ganglia in the walls of the intestines could not fail to produce an effect on the spinal and cerebral centres. The increased action of the kidneys, liver, and other organs after the employment of colonic means was evidence in this direction. This was further shown by the fact that favorable results depended not upon the amount of water introduced, but upon the reaction between heat and cold. Large quantities of water introduced at one time were detrimental. Small quantities frequently repeated had markedly beneficial effects.

In colonic treatment by water or air, single- or double-recurrent tubes might be employed, according to the nature of the case. A tube with a single opening at the end was useless, however, for colonic lavage. On the other hand the author consisted of a rubber tube about a yard long, tapered at the end to an opening with bevelled edges. There were four small perforations opposite each other in a row. Above these there was a large side opening with the edges so sunk as to prevent irritation in introducing the tube. The distance from the end of the tube to the uppermost opening was an inch and three quarters. This tube insured rapid return of the water injected, and there was no danger of suction of mucous membrane by siphonage. There was thus less danger of traumaism and of closure of the end of the tube by the mucous membrane or free wall. This tube insured a more equable distribution of the fluid introduced and was, therefore, of special value in topical applications and in the introduction of food. The double-recurrent tube, or "needle douche," would be found of special value when prolonged irrigation, or lavage, was desired. It had been found particularly useful in obstruction, from whatever cause, by Herschell and others. For the same reason it was of value in appendicular inflammation. The sprinkler at the end had proved useful in atony of the colon and where hot or cold water was needed as a spray or needle douche. In some cases a tube capable of passing the sigmoid flexure might be required. Most of the tubes made passed only to this flexure, but not beyond. The stiff tubes pressed upon the walls and so projected them as to give the false impression that the tube had passed through the flexure. The flexible tubescoiled up and produced the same impression. The author's colonic sound and irrigator could be passed along the colon even as far as the cæcum. It consisted of a double-curved metallic tube about sixteen inches in length, so made as to be passed through the sigmoid flexure. The tube served not only as a channel for the return of fluids injected, but also as a sheath for the introduction of a flexible hollow metallic cable. The distal end of the cable was surmounted by an olive-shaped perforated head. This served as a guide for passing the sound. As the cable was hollow, it might be employed for colonic dissection.

The position of the cable tip could be determined by palpation, especially if the cable was rotated. Since the cable was metallic, it could be employed as an electrode. Food given by this instrument might be distributed over a wide area. Great objection frequently existed to the introduction of water, especially hot water, into the colon. The hot water produced depression and even collapse at times. Warm water was particularly objectionable in this particular. Atony of the bowels from this cause, moreover, was very frequent. Distention of the bowels with water, subsequently withdrawn, would be of value in bowel gymnastics were it not for the fact that, since the water was slow to return and was not compressible, it caused undue distention.

The Centenary of the Birth of Vincent Priessnitz, says the Progrès médical for October 14th, was celebrated on that day in Gräfenberg, in Austrian Silesia, where there is the oldest hydrotherapeutic establishment in Europe. Without any medical learning, says our Paris contemporary, this simple peasant was the first to devise hydrotherapeutic methods which are in use everywhere to-day.

The Czar's Physicians.—According to the Gazette médicale de Paris for October 14th, no other sovereign in the world has so many physicians as the czar. They number twenty-seven and are all selected from among the medical celebrities of Russia. There is first a physician-in-chief; then come ten honorary physicians, three surgeons, and four honorary surgeons; two oculists, a chiropodist and honorary chiropodist; two court physicians and three specialists for the zarina.

Dr. Bingham's Case of Extirpation of the Stomach. —Dr. Charles B. Bingham, of San Francisco, writes to the Boston Medical and Surgical Journal for October
26th that the patient whose stomach he removed, as reported in that journal for May 5, 1898, now nearly twenty months since, has no sign of a recurrence of the disease (carcinoma). Dr. Bingham says that since she left the hospital there has been no restriction whatever as to her food. She eats what she pleases, she keeps house herself, visits her relatives and friends, takes her grandchildren to ride in the cars, and a short time ago, when the California troops came home from Manila, she witnessed the parade, her face beaming with pleasure. That evening the entire city was illuminated, and after driving around the streets she returned home at half-past one in the morning, feeling none the worse for the excitement. Last spring she weighed a hundred and ten pounds; she now weighs a hundred and twelve pounds—a slight gain during the summer. She is now in her sixty-eighth year.

An Important Legal Decision in Medical Consultations.—The Boston Medical and Surgical Journal for October 26th says that a case of considerable interest to medical men has recently been ordered to be retried by the appellate term of the supreme court. A bill of two homeopathic physicians, of seventy dollars for the attendant, and a hundred and seventy-five dollars for the consultant (who made six visits), in a case of fractured elbow, was disputed by the patient, who was left with a stiff joint and interposed with a counter claim for five hundred dollars damages for malpractice. In the sixth municipal court the full amount of the bill was awarded to the physicians. In giving his opinion in favor of reversal, Justice McLean, of the supreme court, concluded as follows: "There was no justification by custom or otherwise in plaintiff's employment of Dr. Roberts (the consultant) without a frank and full statement of the situation to the patient and the defendant (the patient's husband), and learning their wishes concerning the professional persons to be brought in. There can not be properly applied to the facts shown here any custom multiplying ordinary professional charges five or ten times under the shield of a layman's ignorance, because it is subversive of justice that charges should be so largely increased by a custom not made known at all to the patient or to her husband."

Enlargement of the Hospital Corps in the Philippines.—According to the Army and Navy Journal for October 28th, a further increase of the hospital corps in the Philippines is to be made to meet the requirements of a request from Colonel Woodhull, chief surgeon at Manila. Colonel Woodhull has cabled a request for twelve hospital stewards and thirty-two acting hospital stewards and seven hundred privates. This has been to some extent anticipated by the medical department. Colonel Woodhull has now thirty-eight stewards, ninety-three acting stewards, and one thousand and forty-one privates. There are four hospital stewards, ten acting stewards, and two hundred and sixty-eight privates on the way to Manila, and each volunteer regiment leaving for the Philippines has fourteen hospital-corps men. Besides these, a hundred and twenty privates are now ready for departure, and will leave New York within a short time on the transports, going by the way of the Suez Canal.

The Death of the Right Reverend John Wale Hicks, M. D., is announced in the British Medical Journal for October 21st as having occurred on October 11th at Maseru, Basutoland. Dr. Hicks was the Anglican Bishop of Bloemfontein in the Orange Free State. He took the B. A. of the University of London in 1861, gaining honors in chemistry, physiology, and botany; the B. Sc. degree with honors in chemistry and other subjects in the following year, and the M. B. in 1863, when he obtained the gold medal in obstetric medicine. He became M. D. in 1864, and a member of the Royal College of Physicians of London in 1865. Subsequently he entered as a foundation scholar at Sidney Sussex College, Cambridge, and in 1870 he was placed senior in the natural-science tripos, and was at the same time second senior optime. He was demonstrator in chemistry in the university for eleven years, and became a fellow of his college in 1874. In 1871 he took the holy orders, and after holding several curates became dean of his college. In 1881 he was elected a fellow of the Royal College of Physicians. In 1892 he was consecrated Bishop of Bloemfontein. His diocese included the Orange Free State, Basutoland, Bechuanaland, and Griqualand West. In his early days he wrote a textbook on inorganic chemistry. He always retained his interest in the medical profession, and was present at one of the meetings of the Royal College of Physicians during his last visit to England. There are two other bishops who hold the M. D. degree, the Bishop of Ran- goon and the Bishop of Likoma.

Antityphoid Vaccination in the Army.—According to the Army and Navy Journal for October 28th, an investigation is now being conducted by the medical officers of the army to determine the value of the discoveries made some time ago by British medical officers of a vaccine against typhoid fever. Surgeon-General Sternberg received this week several important letters on the subject from the director-general and the deputy director general of the British medical service. Director-General Jamison says that the vaccine has already been used among the British troops, and that it is proposed to inoculate all the British soldiers in India and those going to South Africa. A report sent to General Sternberg and published in the British Medical Journal says: "The advantages which are associated with the use of such vaccines are, first, that there is absolutely no risk of producing actual typhoid fever by our inoculations; second, that the vaccines may be handled and distributed through the post without incurring any risk of disseminating the germs of disease; third, that dead vac- cines are probably less subject to undergo alterations in their strength than living vaccines." The experience with the vaccine in the British service has been that it is entirely free from danger. Constitutional symptoms, consisting of faintness and collapse, begin to manifest themselves generally in two or three hours. Attention is called by Director-General Jamison to the work of Professor Wright at Bangalore and Khartoum. Of eight officers at the latter place, six were inoculated and did not take the disease when it appeared; two declined to be inoculated and both had typhoid fever, one dying from it. Of a total of three thousand troops inoculated more than half never had the fever, while those that did had it only mildly. Professor Wright inoculated two hundred and fifty soldiers of the West Riding Regiment with excellent results. Of two hundred attendants at the Maidstone Hospital, ninety-five were inoculated and none contracted the fever during the epidemic there. Of those who refused to undergo the process nineteen suffered from the fever.
Original Communications.

AN INTERESTING CASE OF SYPHILITIC LEUCODERMA, OR DUNGEON SCURVY, CLOSELY SIMULATING AN ESTHETIC MACULAR LEPROSY.

BY JOSEPH A. SILVERMAN, Ph. G., M. D., PHYSICIAN TO THE MISSION OF THE GOOD SAMARITAN, SAN FRANCISCO.

On June 3, 1899, I was summoned to a hotel in this city to attend one of the guests. I found the patient, an elderly gentleman, extremely prostrated, and upon careful examination pronounced him to be suffering from a severe attack of capillary bronchitis. After attending him several days, I was informed by the manager of the hotel that he had heard from one of the patient's nurses that the patient was a leper, stopping in this city on his way to the leper colony in the Island of Molokai, Sandwich Islands, and asked me to verify the report. Upon questioning my patient in regard to this rumor, he promptly exhibited to me the suspicious spots, and asked me for a diagnosis. After a careful examination I made a diagnosis of syphilitic leucoderma, and finally persuaded the patient to relate to me his interesting history and to permit my assistant to take the inclosed photographs for publication. Thinking my professional brethren would be much interested in this rare and interesting case, I here append the history just as it was related to me by the patient, and without entering into any discussion of the case, in the hope that I shall hear, through your valuable journal, the opinion of any of my colleagues who have had any experience with such cases.

B. W. A., M. D., aged fifty-two years, occupation journalist, was born in England, and after graduating from an English medical college, entered the medical department of the British army, serving in nearly all parts of the world, but principally in India. Some years ago he gave up the practice of medicine and took up journalism as a means of livelihood. Family history very good. He had most of the diseases of childhood, making excellent recoveries. Had typhoid fever thirty-seven years ago, with relapse, but good convalescence. Yellow fever in Jamaica in 1871; no sequelae. Contracted syphilis in 1873, truc lues venera. Specific treatment taken at once and kept up for many years. Contracted morphine habit about twenty-five years ago, but asserts that he has been completely cured and has not taken any for twenty years, during which time he has been in excellent health, showing no signs of old age. In the winter of 1892 he suffered from a sharp attack of bronchitis, with high temperature, making a splendid recovery. In the winter of 1897 he went to Cuba on literary business, and in the month of May, 1898, his camp was attacked by insurgents, his partner killed and mutilated, and he himself severely beaten, kicked, his teeth knocked out and spine injured; he was left naked all night, supposed to be dead. The next day he was put naked into a dungeon with no flooring, no light, and very little air; there was no possibility of sitting down, as his legs were sunken in blue-black sewage of most offensive odor. He was badly bitten by vermin, spiders, etc. After being confined in this place eighty hours, without food or water, he was released. His condition was critical, having a high fever; his legs were badly swollen and ulcerated, and covered with varicose veins. The fever, with delirium, continued for weeks, during which time he was treated with hot fomentations to the legs, aromatics, and febrifuges by a native woman. Later he walked nearly three hundred miles, in short stages, to the coast, tramping by night, sleeping in the forests, with little clothing, but plenty of simple food such as fruits, fish, game, etc. After reaching the coast he sailed for England where he was very ill with symptoms of myelitis, which continued until November, 1898, and were accompanied by intense neuralgia of the cord and facial nerves. At this time there was some loss of special senses, insomnia, complete anorexia, and great nervous excitability. He was examined in London, Liverpool, Glasgow, and Paris for leprosy, but was declared by the best authorities to be suffering from leucoderma or scleroderma, formerly called dungeon scurvy, a condition very commonly found on prisoners in the early centuries confined in filthy dungeons, and so chained that they were obliged to stand or sit in one position. Some fifty cultures all showed negative results. He then came to the United States and was examined by a Chicago physician who diagnosed his case as anesthetic macular leprosy, non-contagious.

At present he is convalescing from his recent attack of capillary bronchitis and is extremely prostrated. He
is anemic, has no appetite, and suffers greatly from insomnia. The urine shows a specific gravity of 1.018 and some albumin. The leucoderma is confined to the legs only, which also show old specific pigmentation.

There is no swelling and no anæsthesia, but hyperæsthesia of the soles of the feet, which he says is congenital. He is recovering very slowly, and is still quite weak, but all symptoms of the bronchitis have left him.

The photographs were taken on June 21, 1899, by my assistant, Mr. E. D. Starbird, and show very clearly the location of the disease on the legs and the character of the spots and lesions.

The dark spots are brown in color and very smooth, and the white spaces are small and covered by rough white scales. There is no œdema or swelling and no loss of sensation. The left leg is a trifle larger than the right and measures thirty-two centimetres in circumference at the knee, thirty-four centimetres at the calf, and twenty-four centimetres at the ankle.

The photographs, while not very clear, show quite plainly the location of the disease upon the legs, the first photograph taking in all of the diseased area, the second one, being enlarged, showing the character of the lesion on the anterior surface of the right leg in the middle third.

Erratum.—On page 727 of our issue for November 11th occurs a Miscellany paragraph on Dr. Bingham’s Case of Extirpation of the Stomach. It should be Dr. Brigham.

AN UNUSUAL ACCIDENT.*

By EWING MARSHALL, M. D.,
SURGEON TO THE TRAVELERS’ INSURANCE CO.;
CHAIRMAN OF MEDICAL BOARD OF HOME FOR FRIENDLESS WOMEN;
PHYSICIAN IN CHARGE OF THE PROTESTANT EPISCOPAL ORPHANS’ HOME,
LOUISVILLE, KY.

I wish to show this patient, who has recovered from a most unusual accident and in the most satisfactory manner:

A. H. V., aged twelve years. On June 16, 1899, he was standing near a shafting. In turning round, the head of a bolt on the shafting caught in his pocket and tore his clothes off him. In trying to save him-

* Reported at the meeting of the Clinical Society, July 11, 1899.
wound the hand and arm around the pulley, finally tearing away the arm, the scapula, and over half of the clavicle from the trunk; the entire shoulder and arm being left upon the field.

When the temporary dressing which had been put on by Dr. Allison was removed, I found a most alarming condition. Much of the crushed clavicle was remaining attached in the mangled tissues. With the splendid assistance of Dr. George W. Griffiths I removed all of the fragments, and then, when the parts were cleared of the mangled tissue, I found that the part of the clavicle remaining had a sharp end, which I removed with bone forceps, rounding it off so as to prevent its doing any injury. How well this was done is shown in the X-ray picture. The great vessel was torn in two just about where it crosses the first rib, or in the third part of the subclavian just before it changes its name to axillary. This I ligated, and it was the only vessel that I thought needed ligating. Right here I desire to say that neither as operator nor as assistant have I seen a case of secondary hemorrhage. In my undergraduate days the bugaboo of secondary hemorrhage was painted in such vivid terms that through the first ten years of my practice it was more or less of a nightmare as a possible sequela to each solution of continuity of any magnitude for which I was in any way responsible.

The parts were thoroughly cleansed with a bichloride solution, about 1 in 5,000. The silk used was put in boiling water, as were the instruments. I wish to take issue with most writers about the use of silk. I am confident, with all due respect to their experience, that silk exposed but a short time to boiling water is as safe as any ligature or suture material that has been given to the profession. In this case, when the dress-

ings were undone on the fourth day and the iodoform strips that had been used for drainage were removed, there was little inflammation in the whole course of the suturing. When the stitches were taken out there was union through nearly the whole extent. The temperature never rose above 100.4° F., and only reached that upon two days. There were extensive abrasions about the face, body, and legs.

On the eighth day the patient sat up on the side of the bed. On the tenth day he walked across the floor. On July 6, 1899, the twentieth day after the accident, he came to my office in the street car, and then walked to Dr. Butler’s office, a distance of nearly half a mile. Dr. Butler kindly took the Röntgen-ray picture which illustrates the case. You will see that the right scapula is entirely gone, and that only about a third of the right clavicle is remaining, and is pulled up by the sternocleido-mastoideus. The photographs were taken on the thirtieth day after the accident. Naturally, you would expect the head to lean to the left, as it receives only partial support from the right sternocleido-mastoideus, and no help from the right trapezius, since the parts of that muscle which aid in pulling the head forward and to the right were attached either to the scapula or to the part of the clavicle that has been removed, but the boy actually carries his head nearly vertical, letting it incline, if any, a little to the right. Fortunately, most of the tissues were removed that would have suffered by the ligation of the subclavian artery, and those remaining will easily be cared for by the anastomosing vessels.

Guaiquin as a Substitute for Guaiacol.—The Indépendance médicale for August 30th remarks that guaiquin ought to prove preferable to guaiacol on account of being free from the odor of the latter drug and free from its caustic property.
FURTHER EXPERIMENTAL RESEARCHES
ON THE
EFFECTS OF DIFFERENT ANÆSTHETICS
ON THE KIDNEYS.*

By ROBERT COLEMAN Kemp, M.D.

About a year ago, during the course of some experiments conducted by Dr. William H. Thomson and myself on the "effects of serum and antitoxine injections upon the circulation of the kidneys," we soon were made aware that the employment of sulphuric ether as an anesthetic produced a specific effect of its own upon the renal circulation, which had to be taken into account before any trustworthy conclusions could be deduced as regards the particular effects of the administration of antitoxines. This action of ether was so often and so uniformly demonstrated as a derangement of the circulation of the kidneys themselves, without a corresponding disturbance of the general circulation as indicated by the blood pressure in the carotids, a condition of complete suppression of urine frequently occurring, that we concluded to institute a similar series of experiments upon the effects of other anæsthetics upon the kidneys. The methods employed and the results secured will presently be described. A no less careful observer than Dr. S. J. Meltzer, whose physiological researches are known to you all, has frequently noted in the course of his experiments that ether causes a marked interference with the kidney secretion, and often a complete suppression of urine. On the other hand, we also noted that chloroform caused but slight changes in the circulation of the kidney, that the volume of the organ was decreased and the secretion somewhat lessened—though complete suppression was never observed. This brought us at once to that long-standing dispute, which is continued among our most eminent practitioners, as to the respective values of ether and chloroform, including the question of the comparative effects produced on the kidneys by these anæsthetics.

As a preliminary, we might advert to certain physiological laws which regulate the secretion of the kidneys, as—

"First, other conditions remaining the same, the secretion of the kidney varies with the quantity of the blood flowing through it; the greater the quantity of blood, the greater the secretion.

"Second, the blood flow through the kidneys, and therefore their secretory activity, may be affected by conditions influencing general arterial pressure.

"The condition of the renal circulation, both in itself and relatively to the general circulation, has an important bearing on the subject."

It can be readily seen that it requires but slight disturbances to unbalance this delicate equilibrium.

Thus, from wetting the feet or by a sudden exposure to a draught of air, there may result an acute congestion of the kidneys; showing how interference with the maintenance of the proper relations between the renal and general circulation influences the renal secretion itself.

When, therefore, the statement is made that the anæsthetic is a rare factor in producing derangements of the kidney functions, or in aggravating those which already exist, it seems at least to run counter to the fact that there is no known anæsthetic, administered in any effective quantity, whatever the method of administration, which does not affect the renal circulation.

Yet some surgeons are very loath to acknowledge that their favorite anæsthetic is a factor, either chief or accessory, in the production of an unsuccessful issue. The partisan of ether has rarely if ever seen untoward results from this anæsthetic—personally, never a death; pneumonia seldom; renal effects seldom and not more frequently than with chloroform; uremia, as a cause of death, seldom if ever. The chloroformist has never seen a death, though acknowledging occasionally rather a "close call"; recovery especially pleasant, as compared with ether; sequelae practically none, contraindications rare.

From the exponent of "anæsthetic mixtures" we learn of an "ideal anæsthetic"; no disagreeable sensations described; and so on. But when, on the other hand, we carefully question the hospital internes, and especially those of from three to ten years ago, before the advent of the skilled anæsthetist, they will tell you of their own knowledge of cases of amputations, operations for strangulated hernia, etc., all apparently successful, but followed by sudden renal symptoms, a little bloody urine on catheterization, and then by the sudden death of the patient. In many of these cases no albumin, or only a trace, was found before operation. The attending surgeons will skillfully perform intestinal anastomoses or resections, but a similar train of renal symptoms will follow. The autopsy will show primary union, no peritonitis, but the kidneys congested. The staff diagnosis is "death from uremia," and as such goes upon the records. In many of these cases no pulmonary

**Fig. 1.—The oncometer.**
ILLUSTRATION OF THE EXPERIMENT, ETHER IN THIS CASE BEING THE ANÆSTHETIC EMPLOYED.

From Dr. Robert C. Kemp's article on the Effects of Different Anaesthetics on the Kidneys.
Fig. 2.—Normal and high-pressure oscillographic curves. 4, normal kilogram oscillograph; 5, tracing after ligature of the renal vein.
complications were found; yet, in spite of facts such as these, some surgeons seem to be still unwilling to impute to the anaesthetic such unfavorable action on the kidneys, and attribute the result rather to sepsis, pneumonia, or other causes.

While these gentlemen are certainly sincere in their views, we think that some of them cannot have investigated carefully the histories of their hospital patients, or the "causes of death," as found in the records of the hospitals they attend.

On the other hand, the skilled anaesthetist, and of such we have a good example with us this evening, is to my mind a most important factor in the successful issue of operations; for the selection of the anaesthetic to suit the operation, and the condition of the patient, are matters on which we should consult with him, after a thorough review of the case. When we compare such an expert with the inexperienced hospital intern, such as some of us were a few years since, whose chief function was literally to soak the patient with ether to avoid reproof for insufficient anaesthesia, we should not be too hard on the intern. Few internes had previously received any practical instruction in anaesthesia, either at the medical schools from which they had just graduated, or from the attending surgeons of the hospitals. Indeed, the selection of the junior as anaesthetist, or his employment at once in severe cases, without such previous instruction, shows a lack of judgment on the part of the chief in charge. In fact, some of the attending surgeons, we are obliged to confess, are far from expert anaesthetists themselves. How often have we seen the "crowding the patient under the anaesthetic" by order of the attending surgeon, or even a demonstration of this procedure by him in person, "as a rapid method of producing anaesthesia," by smothering the patient! Meantime, long dissertations by the surgeon to the "spectators during operation" can not but have a decided bearing on the effects of the anaesthetic, for we find that both the quantity of the anaesthetic employed and the duration of the anaesthesia have much to do with the effects upon the kidneys.

Unfortunately, the skilled anaesthetist is at present in the minority, and therefore we have discussed the question at some length, since by the exercise of proper methods on the part of both the anaesthetist and the operator the dangers of the anaesthetic, in regard to the renal functions, can be much lessened.

Entering, therefore, upon the experimental portion of our paper, I should like to call to your attention the following propositions:

First. Any anaesthetic whatsoever, violating, as it must necessarily do, those laws of physiology relating to the circulation and secretion of the kidneys, and to which we have already directed your attention, may therefore be a "factor, or an accessory factor," in causing disturbances of the renal functions. Hence renal complications may follow any anaesthetic.

Second. Though renal disturbances may follow any anaesthetic, and even cause a fatal issue, yet, owing to such factors as the personal equation of the patient himself, the skill of the anaesthetist, the nature and quantity of the anaesthetic, the length of the operation, etc., there may frequently be no albuminuria or other changes found in the urinary examinations made in our hospitals. Also, slight changes may occur, but they are often evanescent, and by the end of twelve to twenty-four hours all evidences of derangement may have disappeared.

Third. In our physiological experiments, however, we have invariably noted a marked difference in the effects produced on the kidneys by the different anaesthetics, as is shown by a glance at the original tracings and by drawings taken from instantaneous photographs of them, which we herewith exhibit. These drawings are by Thomas Nast, Jr., from photographs taken by Dr. Cunningham. By these methods, in which the conditions respectively of the respiration and of both the general and the particular renal circulation were automatically registered on moving scrolls of paper by instruments of perfect precision, we endeavored to eliminate error through personal equation. As a logical conclusion from this demonstration of marked differences between the anaesthetics as regards their effect upon the kidneys, we would recommend that anaesthetic to be chosen which least deranges the normal action of the kidneys, when the case is of such a nature as to call for special caution to avoid disturbances of their functions.

We wish at the outset to express our indebtedness to Professor John G. Curtis for the free use of the great facilities of the physiological laboratory of the College of Physicians and Surgeons of Columbia University for the experiments, the operations for which were performed on dogs, along with check experiments upon rabbits.

The condition of the circulation of the kidneys can be accurately determined by an instrument first devised by Professor C. R. Roy, of London, and called the kidney oncometer. Besides its extensive vaso-motor supply, the kidney is so vascular that it has been estimated by Landergren and Tiegerstedt that when it is in full functional activity an amount of blood equal to the weight of the organ itself flows through it in a minute's time. Hence it is evident that great changes in its bulk would occur, according to the state of its circulation, and this is so plainly demonstrated by the oncometer that even the rhythmical variations of blood pressure in the organ caused by the movements of respiration are recorded by it. As shown in the cut on page 732 (Fig. 1), the oncometer is a small, bivalved, kidney-shaped metal box, hinged at the back, with a clasp in front, while a grooved notch at the centre of the rims of the valves prevents pressure on the vessels and nerves of the pedicle of the kidney, when the organ is inclosed in the oncometer.
Fig. 3.—Onometric and carotid tracings following the administration of ether.
Lying loosely upon the inner surface of the valves, but fastened to their rims by detachable metal bands, are two pieces of thin soft rubber, which, when filled, so allow a layer of water to be interposed between them and the metal walls of the box that when the two halves are shut down upon the inclosed kidney it rests upon a perfect water pad. A short metal tube in the centre of the upper valve, to which is attached a piece of soft rubber tubing, allows the water in that lid of the oncometer to rise and fall in the tube, according to the expansion and contraction of the inclosed kidney. This movement in the water column is communicated to a column of air farther on in the tubing, which in turn communicates with the air in a closed drum, or tambour, on the upper surface of whose diaphragm rests the long lever of the registering pen, which thus records the oncometric tracing upon a moving sheet of smoked paper. The use of water as the liquid in the oncometer pad is a great advantage over that of oil employed in Roy's instrument, both for convenience and for simplicity, and this improvement we owe to Mr. J. T. Hoyt, the practical electrician and machinist in charge of the physiological laboratory of the College of Physicians and Surgeons.

A special tambour was also made for us by Mr. Hoyt which gave us much better tracings of the kidney than the instruments of Hurtle or Marey.

We give oncometric tracings which illustrate the difference between normal and high-pressure curves (see Fig. 2). The lower tracing represents the lines made by a normal kidney, while the upper one shows the marked contrast when the renal vein is tied; for the consequent great venous congestion and swelling of the kidney in the box forced the water up the tubing so high that the resulting pressure in the air column threatened to burst the drum and raised the line of the tracings above the edge of the smoked paper. As in dogs the kidneys vary greatly in bulk, according to the size of the animal, certain details are secured in Hoyt's apparatus for regulating the amount of water within the oncometer so as to make the pads perfectly adjustable to the kidney.

The secretion of urine was observed as regards rate, quantity, and quality during the experiments by tying a small glass cannula in the ureter leading from the kidney which was not inclosed in the oncometer, so as to obviate the risk of the secretion being affected by the manipulation necessary to include the kidney in the box. We think that this requisite precaution has not been observed by some experimenters. The drops flowing from the ureter impinged upon a delicate lever with an oblique spatula-shaped extremity; the fulcrum of the lever being the drum of a tambour, which communicated the stroke of the falling drops through an air column in a rubber tube to the drum of a second tambour, on which a lever pen registered every drop by a mark resembling an inverted V along a line on the smoked paper above the kidney-pulse tracing. Meanwhile, the drops of urine falling on the spatula end of the first lever flowed off into a cup, where they were collected for chemical and microscopical examination.

For the purpose of a constant comparison between the blood pressure in the kidney and the general blood pressure, a small glass cannula was introduced and tied in the right carotid, and to the cannula was attached a piece of rubber tubing, both it and the cannula being filled with a soda solution to prevent blood clotting. The rubber tube was then attached to a flexible lead tube, which was connected with a Ludwig's mercurial manometer, so that every pulsation in the carotid was communicated through the soda solution to the mercury in the manometer. A float on the mercury in the manometer carried a fountain-pen attachment which registered the carotid pulsations with ink on the paper of the revolving or Ludwig's kymograph. The normal height of the blood pressure was first carefully noted in each dog. This height varied from one hundred and twenty-five to one hundred and fifty millimetres, and, the standard height in each animal being thus noted, variations from this could then be readily observed.

To insure uniformity in the administration of the anaesthetic, as well as to have ready recourse to artificial respiration when needed, a preliminary tracheotomy was performed in all cases. The tracheotomy tube was tied in firmly, and to it a piece of soft-rubber tubing was attached, and the anaesthetic was administered through this tube. The frontispiece illustrates the experiment, either in this case being the anaesthetic employed.

The glass V attachment to the tracheotomy tube to secure respiratory movements we found interfered with our results. The polygram, a small air bag attached to the chest and connected with a tambour and pen, was employed at times. The one I show was constructed in an emergency out of a bicycle pump by Dr. Cunningham.

As a matter of interest we have here this evening a special apparatus devised by Mr. Hoyt as a regulator for artificial respiration. By a system of gearing, a friction disc and a peculiar valve with shuttle action, artificial respiration from twenty to a hundred and twenty to the minute, and at varying volumes, can be given to suit the normal respiratory movements of the animal to be employed in the experiment. Even the normal pauses of inspiration and expiration are produced. Mr. Hoyt will explain later its action to those who take interest in the matter.

In all such experiments, and notably in regard to the action of anaesthetics, a chief indication is to avoid delay as much as possible, for prolonged anaesthesia with any agent induces modifications from the first effect. In these operations it was found possible to complete all the incisions and make the connections between the different parts of the apparatus, with proper regulation
and starting of the tracings, in twenty minutes. You
will kindly observe Mr. Hoyt’s demonstration, and note
how, by a simple device, with a soft-rubber bag with in-
flow and outflow lines and with a Davidson’s syringe,
he practically reproduces our experiments with the kid-
nneys.

Effects of Ether.—The results from the adminis-
tration of ether obtained from experiments on ten dogs
were remarkably uniform, and are well illustrated in
Fig. 3 (page 735).

Carotid Tracings.—The effect of ether on the gen-
eral blood pressure, as shown by the carotid tracings, is
to raise the pressure from the beginning, even under
mild anaesthesia. When the ether is pushed, the carotid
tracings rise again slightly. When the ether is removed,
there is a moderate fall.

Kidney Tracings.—Under moderate anaesthesia
there is at first a slight rise of the tracings from the
base line, corresponding to the carotid tracings, but
as the ether is pushed a marked contrast from the
simultaneous carotid tracing is noted by a great fall in
the oncometric curve down to the base line and even
below it. If the anaesthetic is thus kept up the waves
grow progressively shorter, or even disappear for a few
seconds. If the ether is then suspended it takes from
thirty seconds to two minutes for the kidney to re-
cover, when the tracing line begins to rise again, to be
again depressed if ether is readministered. This ef-
fect was noted over and over again, and from its un-
iform contrast with the corresponding carotid tracing
it shows that this effect upon the kidneys is specific,
and, what is more, this specific effect can be separately
noted when ether is mixed with other anaesthetics.
Clearly, it can not be imputed to the increased tension
caused by ether; for we have the typical ether kidney
tracings appearing during the use of the mixtures with
chloroform, when there is a reduced tension from the
chloroform heart, as with the use of the A. C. E. mix-
ture.

The renal secretion under ether, determined as above
described, was first an early diminution in the number
of drops from the cannula in the ureter. The secre-
tion diminished progressively, as the oncometric curve
dropped toward the base line, until finally, under free
and continuous etherization, a complete suppression oc-
curred. These are shown in the figure, “inverted V’s,”
on the upper line—three drops before ether was pushed,
with only two drops in about four times the intervals
afterward, and only one drop toward the end of the trac-
ing. Albumin appeared early even under moderate ana-
esthesia. This increased under deep narcosis, until
just before the suppression it amounted to about sixty
per cent. in volume.

Chloroform.—The experiments with chloroform
were performed on six dogs.

Carotid Tracings.—As seen in Fig 4 (page 736).
there is an evanescent rise, lasting only two or three sec-
onds, when but a slight amount of chloroform is admin-
istered, soon followed by a fall of pressure. As the
chloroform is pushed there is no initial rise, but the fall
becomes more marked. As soon as the chloroform is
suspended the pressure rises again. There can be no
question that the fall is due to the depressing effect
upon the heart.

Kidney Tracings.—In contrast with ether, the kid-
ney tracings closely correspond with the simultaneous
carotid tracings. The kidney tracings become shorter
as they approach the base line, but they do not be-
come abolished, nor do they ever fall to the base line
as with ether, but simply remain parallel to the record
of the general circulation.

The renal secretion remains copious in amount and
begins to diminish only as the general circulation be-
comes much depressed, the urine continuing to flow
nearly to the time of death.

Albumin appeared only after prolonged narcosis,
and then in but small amount, though the general cir-
culation had become dangerously lowered.

(To be continued.)

THE RELATION OF PATHOLOGICAL CONDITIONS
IN THE ETHMOID REGION OF THE NOSE
AND ASTHMA.
TREATMENT.*

By F. H. BOSWORTH, M.D.

This whole matter, it seems to me, depends upon a
proper appreciation of the great respiratory function
of the nose and the necessary and very intimate connec-
tion between the nasal apparatus and the bronchial mu-
cous membrane. At best, we can make little out of the
bronchial tubes excepting as mere conducting tubes.
We find no special functioning apparatus until we get
to the air cells, and these are not involved in an attack
of asthma. This has a decided bearing on treatment,
in that any disturbance of the nasal mucous membrane
constitutes a disturbance of the great respiratory func-
tion of this membrane, which has to pour out from
twelve to sixteen ounces of watery fluid upon the sur-
faces of the turbinated bodies to saturate and moisten
the air which passes into the bronchial tubes. This
presupposes an intimate connection between the mu-
cous membrane of the nose and the mucous membrane
of the bronchial tubes. The disturbance of one part
means a disturbance of the other part; that is to say, a
congestion of the nasal mucous membrane creates a
marked tendency to a like congestion in the bronchial
mucous membrane, while a healthy functioning con-

* Read before the American Laryngological Association at its twenty-
first annual congress.
condition of the mucous membrane of the nose tends to a
like healthy condition as that of the bronchial tubes. A
diseased condition of the mucous membrane of the nose
tends to produce disease of the bronchial mucous mem-
brane. It seems to me that in this fact, established by
clinical observation, lies the basis for our consider-
ation of the relation between asthma and disease of
the nasal cavities. If we acknowledge this, it seems to
me we are ready for a clearer comprehension of what
the true relation is between these two regions in this
neurotic disease we call asthma.

Dr. Swain, in discussing the pathological aspect of
the question, now considers it edematous hypertrophy
and polypoid degeneration, which I think in this dis-
case must be a vasomotor paresis, a dilatation of the
blood-vessels. I am glad to hear less talk of muscular
spasm. He is the only man in my presence who has
disturbed my conviction that an attack of asthma is a
vasomotor paresis of the blood-vessels of the mucous
membrane of the bronchial tubes rather than a spasm of
the bronchial muscular fibres. We know that an attack
of hay fever is a vasomotor paresis of the blood-vessels
of the mucous membrane lining the nasal cavity. In my
previous writings I have designated hay fever as a vas-
omotor rhinitis. This establishes their intimate con-
nection, and if I am correct in this view of it, it therefore
follows that the treatment which is indicated in these
cases becomes notably clearer. We talk about edema-
tous hypertrophy, polypoid degeneration, and nasal
polypi as intimately associated with asthma. Clinical
observation has taught this, and there can be no ques-
tion of the fact, but I think, and my conviction has been
for a number of years, that we can go still further.
I believe polypoid degeneration of the mucous mem-
brane of the nose, edematous hypertrophy of the mu-
cous membrane of the nose, and nasal polypi all in-
dicate and are clear symptoms of ethmoiditis. We
oftentimes see cases of asthma that are relieved by the
removal of polypi, yet the asthma recurs. Why? Be-
cause we fail to recognize the fact that the polypi pres-
ent in the nose are only symptoms or manifestations of
disease in the ethmoid cells, and in removing simply
the polypi we have not fully carried out the clinical
indications. We have neglected to do our whole duty
when we remove the polypi alone. We must accept
the existence of polypi as indicative of ethmoiditis, a
chronic inflammation of the mucous membrane lining
the ethmoid cells. By making the radical operation we
not only remove the polypi and protect the patient
from further recurrence of them, but we cure the
asthma. How shall we do that? It requires pretty
radical treatment, and I have tried various methods.
There are two ways in which ethmoiditis manifests it-
self in the nose. The first and early indication is in the
polypoid degeneration of the mucous membrane cover-
ing the middle turbinate bone. This I have come to
recognize as almost pathognomonic of the existence of
a similar degeneration of the lining of the ethmoid
cells. If we go over the plates of Zuckerkandl we shall
find many cases of cross sections of the head in which
there is a great hollow middle turbinate, a great egg-
shell, so to speak, projecting into the cavity of the nose,
bulging out the septum, and establishing contact be-
tween the turbinated body and the nasal septum. The
ethmoid cells become distended and burrow out, as it
were, into the middle turbinate in such a manner that
the middle turbinate becomes the outer limit of the eth-
moid cells. In another series of these plates we observe
the ethmoid cells distended in such a manner as to crowd
the middle turbinated body out en masse into the cavity
of the nose and cause it to impinge upon the septum.
These two conditions are the ones which, from clinical
observation, I recognize as constituting ethmoiditis, as
evidenced by the fact that the middle turbinated body
is covered by edematous hypertrophy. Why does this
occur? I take it, it occurs simply because the normal
orifices of the ethmoid cells have become occluded by a
mild inflammation. This mild inflammation may be
the result perhaps of clots. My impression has been
for a long time that clots are a symptom rather than a
result. I think that in most instances it is one of the
adventitious results of simple chronic hypertrophy of
the nasal mucous membrane, causing occlusion of the
anterior and posterior orifices of the ethmoid cells. The
result of this occlusion is the establishment of a mild
chronic inflammation which, in these closed cavities,
takes on a certain edematous character. An inflamma-
tion within the closed cavities or accessory cavities be-
comes practically a polypoid degeneration of this mucous
membrane. The closure causes intracellular pressure,
which in turn causes distention of the soft, flexible
parts and extension of the ethmoid cells, crowding the
middle turbinated body into the nose and against the
septum. We now have a curious chain of symptoms de-
veloping. Why neurotic symptoms are so closely asso-
ciated in so large a number of cases with ethmoid in-
flammation I do not know, nor do any of us know, I
take it. We have ample clinical evidence for the state-
ment that the nerve centres which preside over the vasomotor
nerves must be in close proximity to the ethmoid
cells. The first thing that occurs with swelling and
distention of the ethmoid cells in so many cases, espe-
cially if there is a neurotic habit, is something which
disturbs that control which the vasomotor centre exer-
cises over the blood-vessels of the nasal membrane, and
we have sneezing, we have asthma, we have a disturb-
ance of that nice relation which exists between the
mucous membrane of the nose and the bronchial mu-
cous membrane, upon which the integrity of the bron-
chial mucous membrane depends. However that may
be, and whatever the train of symptoms that is set up
by this distention of the ethmoid cells, certainly the in-
dication is clear. We have to cure the ethmoiditis, the
disease in the ethmoid cells, and it has been my firm
conviction for a number of years that the prominent indication is to relieve intracellular pressure. How is this to be done? It is simple enough, but it must be done radically. When it shows itself in the form of polypi in the nose, we must not content ourselves simply in removing the polypi, which are but a small portion of the disease. We must go further than that and attack the cell cavities. If we have a mass or masses projecting into the nasal chamber, we fit a snare around them and thoroughly remove them, uncapping them, and thus open up the cavity. We thus remove all points of contact; yet mere points of contact in the nose I regard as harmless. We should remove these points of contact because they are the result of encroachment on the normal nasal chamber, and by removing them we reestablish the normal nasal lumen. I say we should go further and open up the cells of the ethmoid. How? I know of but one way. I can not easily or efficiently manipulate round cutting forceps in the middle meatus of the nose. Well, you may say, we should use curettes or gouges.

In this region we are operating in a very delicate part, and I can not manipulate gouges with any satisfaction. We have not only got to gouge out more or less of the ethmoid cells, but to break up the little trabecular walls, all of them. We must relieve the intracellular pressure, and we have this pressure in a large part of the ethmoid cells, and consequently the indications are to break down these trabecular walls. My experience teaches me that by all odds the most delicate, truest, and safest instrument with which to do this is a burr. I use a series of burrs, from the sixteenth of an inch in diameter to about a quarter of an inch in diameter, rounded and ovoid in shape. They are mounted on a dental engine, or they may be attached to an electric motor, if you want to be modern and scientific. When you get cases in which the turbinate body has protruded into the nasal cavity you can not snare them so easily, and I prefer to use the burr. By means of the burr you are able to grind down these trabecular walls. I have not met with any accident in any of a large number of cases on which I have operated by this method.

A word or two with reference to those cases where the polypi are situated in the superior meatus. These cases trouble us and are difficult to deal with. Those are the cases which show clearly that the polyloid tissue was developed, or rather that the intracellular pressure was developed, in the posterior ethmoidal cells which have become occluded, and the polypi have made their way out of the posterior ethmoidal cells into the superior meatus. Thus the ethmoid cells are distended where the superior meatus is exceedingly narrow, and you never get large polypi. I have rarely seen in this region polypi larger than the size of a lentil or a small split pea. These cases are difficult to deal with. It is the anterior ethmoidal cells which are involved in probably nine cases out of ten, and it is these, in which polypi are projecting well into the nasal cavity, that we can treat most easily. I am an earnest advocate of the use of the burr, which I find a most efficient instrument for breaking down the trabecular walls of the ethmoid cells. It is the safest way to do this work, and the burr does its work more thoroughly and more safely than any other instrument with which I am familiar.

Inflammatory disease of the ethmoid cells, or ethmoiditis, is a common affection. It is vastly more common than we have been taught to suppose. A great many cases of colds in the head are really attacks of acute ethmoiditis. Chronic inflammatory diseases of the ethmoid cells and non-purulent disease of the ethmoid cells are affections which nowadays are easily recognized by us. Such conditions being recognized in connection with cases of asthma, especially if the attacks are relieved temporarily by the local application of cocaine, we have every reason to give such patients a fairly good prognosis, and to promise a cure by the treatment of the ethmoid cells. Furthermore, we should always bear in mind that in those cases in which we remove the polypi and do not cure the asthma, the polypi are simply a local manifestation of the disease farther on, and we must not only remove these polypi thoroughly, but treat the ethmoid cells as well. We can remove the polypi and relieve the asthma in most cases, unless we have those intensely neurotic patients to deal with who can get up an attack of asthma on the slightest provocation, and from even trivial disturbance of any of the other organs of the body. These are the cases which tax and baffle us. The ordinary case of asthma occurring in connection with recognized intranasal disease I regard as curable in the large majority of instances, and I am confident that many of the cases which have failed of relief at our hands heretofore have failed because we have not sought the source of the disease deeply enough.

THE SHELDON MURDER TRIAL.

A REVIEW OF THE MEDICAL EVIDENCE RELATING TO PISTOL-SHOT WOUNDS OF THE HEAD.

By CHARLES PHELPS, M.D., Surgeon to Bellevue and St. Vincent’s Hospitals.

[Concluded from page 675.]

In order to arrive at a better knowledge of the sufficiency of the experiments, which were instituted to determine the significance of the lesions observed, a considerable and probably adequate number of additional experimental observations in connection with this review have been made upon the cadaver. A Colt’s five-chambered revolver of 0.30 calibre made in 1875, in all respects of the same character and dimensions as those employed by the prosecution and defense, and charged with old cartridges, was used. The subjects were all recently dead, uninjected, without obvious signs of decomposition, not previously frozen, and were
warmed and dried before they were shot. The wounds were all made upon the head, with the exception of a limited number which were made upon the body, simply to compare the effects of very old with new powder, and which were not otherwise regarded.

There were certain of the lesions which have been enumerated as being present or absent in the case at issue, which are often characteristic of pistol-shot wounds made upon the cadaver, and sometimes of wounds of the living subject, which are without import in the present investigation. The smoke stain, which is not tenacious, can not be expected to survive a free external hemorrhage, and is certain to be removed by even moderate ablation. Three grains of powder upon the surface are not only readily removed by slight disturbances of the body, but leave no stain after their removal. The radiation of the hair, which is of frequent occurrence at the shorter ranges, is inconstant. Brain matter may or may not be extruded from the wound, and fragments of bone of varying size are driven through the cerebral tract at all ranges and with all calibres of bullet. The size and outline of the cutaneous and osseous wounds are not dependent in any degree upon range except with bullets of the larger calibres. These facts have been demonstrated in an extensive series of observations recently published,* and are verified in the later experiments made with bullets of 0.30 calibre for this review of a special case. It has been equally demonstrated that a certain amount of singeing of the hair, and a certain proportion of powder grains partially imbedded in the skin, may be so washed away as to leave no traces. This may be done with water, or soap and water, or with embalming fluid, though the last has no special efficacy in this way. If, however, the burning of the hair extends far beyond its tips, it will still be discernible; or if the grains are deeply imbedded they will leave perceptible pittings of the skin. The instances in which an appreciable proportion of the grains does not wash out are exceptional. At ranges of five and six inches, in which they are exceedingly numerous and are concentrated within an area of half an inch to two inches and a half, an estimated one third to one half disappeared in each one of twenty and more observations. In like manner small lacerations, or a staining or charring of the edge of the wound, may be lost through necessary incisions and manipulations made in the course of ante-mortem treatment or of post-mortem examination.

The hypotheses which were formulated, denying and affirming that the wound was the result of a contact shot, were predicated upon the existence of identical lesions, with the exception of singeing of the hair, which was not included in that of the prosecution, though attested as a fact by its medical witnesses. If the positive and negative conditions which are demonstrably without significance are excluded, there will remain for explanation the presence of a discolored spot upon the top of the ear, some isolated powder stains upon the ear and temple, the burning of the hair, the discoloration and contusion of the subcutaneous tissues, and the absence of a certain number of imbedded grains, of burning of the skin, of laceration of the wounds, and of the infiltration of the wound and subcutaneous tissues with powder gas, smoke, and grains.

The ascription by the prosecution of the discolored spot upon the ear to injury received in the passing of the bullet seems more credible than the suggestion of the defense that it was a post-mortem lesion; and if, as stated, chemical examination disclosed unmistakable evidence of lead, it leaves little room for doubt that the part was contused during life, but it proves nothing more; it determines neither the range of fire nor the manner of injury. A shot might as conceivably graze the ear if fired at a range of one or more inches as when coming from a longer distance, and even in a contact shot contusion might be caused by a recoil of the pistol. The presence of lead in the tissues of the ear is indeterminate of range, since lead particles as well as grains of powder may escape through the space between the barrel and the chambers and be found behind whatever line may have marked the position of the muzzle.

The two stains upon the ear and the one upon the temple discovered at the first necropsy and described as "being such as grains of powder would make if they struck the skin when not ignited" were not noted in the examination of the body made after exhumation, and it may be assumed had disappeared. As they were not burns they were evidently from powder grains or smoke, and though more persistent than usual were entirely removable, as indicated in general statements previously made. A few such isolated grains at a distance from a contact wound are occasionally observed in the use of this pistol, and therefore are not significant of range. An unnecessary difficulty seems to have been made in explaining the existence of such grains at a point directly behind the wound of entrance; but the fact, though it were incapable of explanation, still remains, and the fact, not its explanation, is the one thing of importance.

The burning of the hair may be held in view of a very great number of experiments with pistols of all calibres, including that of 0.30 calibre, as of especial significance among the enumerated lesions. It has been found to occur at contact, and to be limited to a definite range which increases with the calibre of the bullet, and extends from three inches with a bullet of 0.22 calibre to fifteen inches with one of 0.44 calibre of the most effective type. In seventy-five observations made with this pistol of 0.30 calibre at ranges from contact to six inches inclusive the condition of the hair was noted. In thirty-two additional observations made at ranges of six inches and a half and more it occurred

* Phelps. Tramatic Injuries of the Brain, etc., part ii.
in no instance. The burning of the hair at contact range, which was observed in less than half the cases examined, was limited to a few hairs at the margin of the wound; at ranges of a fourth of an inch to two inches it was invariably in a series of twenty-three cases, and was oftener than otherwise a mere singeing of the tips, and was limited to one aspect of the wound or to an area of an inch or less; at ranges of three to five inches it was no longer constant and was slight and confined to the margin of the wound. At a range of six, or at six inches and a half, the hair was no longer burned. The results obtained by the chief witness for the prosecution in the small number of experiments upon the cadaver made by him are so different from those just recorded as to be difficult of comprehension. He found in every case, from contact to a range of four inches, the hair burned to a crisp down to the scalp on every side of the wound in an area of an inch and a half to two inches, and blown violently away from the wound. A large number of observations probably would have modified these generalizations. The additional statement that he had burned hair with this revolver and ammunition at twenty-six inches is explicable only upon the supposition that by the removal of the hair from the head, or in some other way, the conditions were made abnormal. The alleged fact that two particles of powder will burn twelve hairs at a distance of twenty-four inches, whatever may be thought of its manner of demonstration, is not paralleled by any known observation made upon the cadaver.

The apparent burning, but not burning, of a lock of hair at some distance from the wound was probably occasioned, as the witness suggested, by a process of crimping to which it was subjected after death. It was not claimed by the prosecution that the singeing of the hair at the margin of the wound was due to the same cause. The obvious fact that the heated but unburned hair had been rolled about some object, while the singed hair, burned only at its tips, stood upright upon the anterior aspect of the wound in the course of the bullet, would make such a supposition untenable, even had the burning not been discovered as it actually was before the crimping had been done.

The condition of the subcutaneous tissues failed to receive the careful attention which it demanded. The discoloration and appearance of contusion which they presented at the first necropsy can be ascribed only to hemorhage and consequent injury to structure, if it be true, as stated, that at the second necropsy no evidence of the deposit or infiltration of powder could be detected. Such appearances of contusion as were described have been experimentally produced at short range, but have not been recorded as occurring at a range beyond six inches. The subcutaneous lesions with this calibre conform generally to those observed with other calibres of bullet. In an examination of the same one hundred and seven cases which were scrutinized for burning of the hair, there was powder infiltration of the superficial fascia or temporal muscle, or of both, too great to be entirely removed by either hemorrhage or ablation, with every contact shot. At a range of a fourth of an inch there was a staining of the temporal muscle or osseous surface, or a simple blackening of the bullet track in every instance. At ranges of half an inch and an inch there was no more than a staining of the bullet track, and not always that. At longer ranges there were no powder deposits and nothing observable aside from the contused wound itself, but bits or fragments of lead variously deposited above or below the pericranium. While a considerable deposition of powder or of the products of its combustion may be excluded in this case, it is not certain that a mere discoloration confined to the bullet track may not have been so concealed by hemorrhage or by manipulations of the wound, as to have been impossible of detection at either necropsy. If from this negative indication, therefore, a contact shot can not be admitted, it is still possible that the shot may have been fired at a range of a quarter of an inch to an inch; and if this were not actually the case, the contusion of the soft parts, so far as it may be judged from the results of experiment, affords positive evidence that the range was not greater than six inches.

The cranial contents seem to have been but cursorily examined. The softening which the brain is said to have suffered was apparently rather a lack of cohesion in its parts from extensive laceration, and would increase the probability that the range was short.

The negative results of an examination of this case are also significant.

It has already been stated that the size of the cutaneous and osseous wounds does not depend upon range, even at contact, except with the larger calibres of bullet. This statement also applies equally to laceration and comminution. Laceration, which is almost constant at contact with 0.38 to 0.44 calibres, is exceptional with 0.22 calibre. In fourteen observations made at contact, with this pistol of 0.30 calibre, the external wound was trivially lacerated in six only, and the greatest diameter noted did not exceed that of a wound made at a range of thirty inches. In twelve of these observations, in which the osseous conditions were remarked, there was comminution in only three, and in several in which the outline was circular the diameter was not greater than may be observed at any of the longer ranges. The absence of laceration of the soft parts, therefore, in any instance of the use of this calibre of pistol, like the size and form of the osseous wound, is without significance.

The burning of the skin is confined to a still narrower limit of range than the burning of the hair, and is of proportionately less frequent occurrence. In contact shots with the pistol of 0.30 calibre, except in a single instance in which there was a stain of doubtful character upon the skin of the forehead, it was never
was not the result of a shot fired at contact. In a very
great number of experiments made upon the cadaver
at contact, with pistols from the smallest to the largest
calibres, a considerable amount of powder has always
escaped combustion, and has been somewhere appreci-
pably deposited, either upon the cutaneous surface or in
the substance of the subcutaneous tissues, above or be-
low the temporal fascia.

The generalization made from the observations of
the medical witnesses for the State, in which the effects
of shots fired from contact to a range of four inches are
grouped and, with certain exceptions noted, made to
appear essentially the same, is not true in fact and is
mischievous in effect. The results of shots at contact
or at a fraction of an inch, when compared with those
fired at a range of three to four inches, are as strongly
contrasted as any which are to be observed in the whole
field of experimentation. The infiltration of the sub-
cutaneous tissues, the usual characters of the wound,
the extent of burn, and the area and number of super-
icially imbedded grains characteristically differ. It is
by no means to be inferred because there is reason to
believe that a shot was not fired at contact that its
range might not have been less than four inches; and
yet this inference seems to have been the sole basis of
exclusion for such ranges in the present case.

The assumption that the shot was fired at a range
of two or three or more feet is made untenable by the
fact that the hair was burned and the subcutaneous tis-

tues were confused. The reasons for making this state-
ment positive have been previously set forth and need
not be recapitulated. A lead stain and an inversion of
the edge of the subcutaneous wound, and a few sparsely
scattered grains of powder upon the surface, some of
which may be imbedded, are the only positive indica-
tions of such ranges; and these are not constant.
A burning of the skin or hair, or a subcutaneous contu-
ion or infiltration of powder, whether burned or unburned,
is therefore sufficient evidence in any case that the
range has been short. The results of twenty or more
shots fired with this pistol are substantiated by a much
greater number of observations made with others of
various calibres.

Certain opinions and assumed statements of fact,
which as collateral evidence form parts of the record,
can not be accepted without question.

It was testified by a manufacturer that the strength
of powder is lessened by age, and that when old its com-
bustion is slower and its burning qualities much greater.
This may have been proved for the burning of straw-
board with which his experiments were made, but it is
not true for the human body. In numerous experimen-
tes made with the special object of determining this point,
no appreciable difference has been observed in the range
at which burning of the hair or skin occurs, in the area
or density of smoke stain, or in the deposit of powder
grains, whether recent cartridges were used or those-
filled with powder known to have been made thirty-five years or more ago. These observations were at several ranges, and with cartridges of different sizes. In experiments made at the rifle range in Salem, Massachusetts, powder which was fifty years old was found to have suffered no deterioration. It is probably the fact that powder which has not been exposed to dampness or penetrated by the lubricant which covers the cartridge is unaltered by the mere lapse of time. The modified effects of powder which has been subjected to such influences are not to be determined from inference, but can only be ascertained by direct experiment. A series of such observations, therefore, forty-two in number, has been made with cartridges of different calibres containing damaged powder. Tests were made with cartridges in which the powder was still damp, and with others in which the powder, though caked, had become dry. It will be sufficient for the present purpose to state the general results of these experiments without analyzing the statistical data upon which they are based. The essential change which is noted in the effects of cartridges by a dampening of their powder, or by a persistence of its caking or concretion after it has become dry, is a diminished penetrating force given to the bullet, which with all calibres and at all ranges is proportionate to the percentage of powder which has been rendered incombustible and therefore inert; and as under the same circumstances of exposure individual cartridges suffer in different measure, and perhaps some of them not at all, it is impossible to assume the degree or even existence of this loss of energy in a given instance, or in general to formulate an average of its results. In a review of forty-two observations, in which the cartridges were known to have suffered material alteration, whatever peculiarities they present will be found to depend upon the deficient energy of the damaged powder. The percentage of penetrations and perforations of the cranium was much smaller than in the use of sound cartridges of the same calibres. If the powder was dry and not greatly caked the difference was minimized or inappreciable. The imbedded grains, though occurring in the same areas, were finer, rather fewer in number, and could be washed away in larger proportion. The smoke stains and subcutaneous lesions were not appreciably modified, and the cutaneous and osseous wounds were of the same average dimensions. In case of powder which, though caked, had become dry, the hair was not burned at longer ranges, but if the powder was still damp the range at which burning occurred was slightly extended and its severity was increased; and the burning of the skin under the same circumstances was similarly affected. The relation of these facts to the case at issue is obvious. In that case the opposite cranial wall was shattered, and as with the pistol used perforation, even with the use of sound cartridges, is infrequent, the powder, though old, must have been dry and not sufficiently caked to impair its energy. It follows that the conclusions derived from experimental observations made can not be invalidated on the ground that more recent cartridges were employed, and that the range at which hair can be burned (to the key of the solution of the problem of possible suicide) could not have exceeded five inches with the use of such cartridges as were in the possession of the defendant.

The testimony of the same gentleman as to the distance to which flame and sparks are projected, and his fanciful explanation of the often greater size of contact wounds than others by a loss of equilibrium in the bullet which it has no time to regain, are immaterial to the question to be solved. A statement of fact made by him, that in all cases when he had fired at blotting paper at contact a blackening was found on the first finger of the right hand between the first joint and the knuckle, is, however, pertinent and of serious importance in connection with the attested circumstance that the corresponding finger of the deceased was clean. The medical witnesses for the prosecution corroborated and emphasized this experience in testifying that the deposit upon the finger was more pronounced when shots from this pistol were fired into the human body, and was denser when they were fired at contact; and still further, that it was invariable, and could not be removed by washing the part. The medical witnesses for the defense, on the other hand, made special experiments with the same pistol and with old ammunition, in a certain number of which no trace of deposit could be detected on the trigger finger; and one witness, in a final instance, was enabled to exhibit to the jury his finger, which had been unwashed and carefully protected from change, still unsoiled. In the later experiments made in the study of this case some soiling of the trigger finger, however slight, has been found in every instance in which it has been sought; but when trivial, it has not been usually incapable of removal by washing. The at least one demonstrated exception to what seems to be the general rule as to a finger deposit is sufficient to invalidate any conclusion which it might otherwise suggest; and as the stain may be removable by even ordinary ablution it is not an unwarrantable assumption that it may have existed in this case, have primarily escaped attention, and have quite disappeared before the final examination of the body when for the first time this point was given any special attention.

It is not strange that differences of opinion should have existed among the medical witnesses, and that opinions should sometimes have been stated so unrestrainedly as to have assumed the form of statements of fact. It is not certain, for example, that living hair is more readily burned, or that living skin is more penetrable by powder grains than that which is dead. These are questions to be determined only by actual observation, and a large number of cases of suicide and homi-
cide, a larger number probably than were compassed in the experience of the witnesses who testified so positively pro and con, have not been sufficient to give them definite answer. The accidental conditions of the hair, whether it be wet or dry, smooth or fluffly, fine or coarse in texture, are obviously influential, both in the living and in the dead, in determining not only the area and degree in which it may be burned, but the range within which it occurs. These conditions being the same, if slight differences exist, dependent solely upon the fact of life or death, they can not be ascertained with certainty, since the exact range at which a suicidal or homicidal shot has been fired is always inferential; the victim, if he survives, usually says the pistol was held closely to his head, and is unable more nearly to approximate the distance. The same difficulty from inability to fix the range with precision is encountered in deciding the comparative penetrability of living and of dead skin to grains of powder. It can be surmounted in some degree by the observation of pistol-shot wounds made upon parts immediately after their amputation during life, and while the skin is still warm and presumably but little removed from its normal condition.

Several experiments were made in order more clearly to determine this point; one of these was made with the revolver of 0.30 calibre heretofore employed. A section of skin and subjacent superficial fascia was removed from the mammary region of a woman thirty years of age, of average weight and in perfect health, who was suffering from an abscess beneath the pectoral muscles. The skin was of medium thickness, soft, pliable, delicate in texture, and of absolutely normal character. The part removed was of oval form, and four inches and a half by two inches in its longest diameters. It was shot ninety seconds after its removal from the body, with a bullet of 0.30 calibre from a short cartridge filled with black powder, thirty-five years old, at a range of an inch. The smoke area was oval, radiated, and six by four inches in diameter; the wound was an eighth by three sixteenths of an inch in diameter; the burned or black area was a half by three quarters of an inch in diameter, and the burn was extended by a yellow scorched area to an inch and a quarter. There were no grains free upon the surface, and those imbedded which were perceptible were confined to the margin of the black area and were about twenty in number. Five days later the skin, which had been meanwhile refrigerated, was again shot at a sufficient distance from the original wound with the same pistol, at the same range, and with a cartridge of the same size loaded with the same powder as before. The wound and burned areas had the same diameters as before, but the black area was much less deeply charred and the yellow area was less uniformly and more lightly scorched. The imbedded grains were perceptible throughout the black and extended farther into the yellow area, and were from seventy-five to one hundred in number. Though the number of grains was undoubtedly greater in the second experiment, many in the first may be assumed to have been concealed in the more deeply charred surface. In the first case seven, and in the second eight, grains penetrated to the subcutaneous tissue.

In a similar observation made with a bullet of 0.38 calibre, at a range of six inches, a piece of normal skin from the mammary region was shot with a new cartridge a minute and forty seconds after its removal from the body. The area of smoke and grains was two inches and a half by two inches in diameter, the wound of entrance an eighth of an inch in diameter, inverted, and lead stained, and the skin slightly scorched in an area of half an inch by five eighths of an inch, and at a distance of half an inch from the wound. The number of grains imbedded was about two hundred. After ablation, the scorching of the skin was barely perceptible and in diminished area; the smoke stain and about twenty-five per cent. of the grains were removed; and it was found that no grains had perforated the skin. Five days later the same piece of skin, which had been refrigerated, was shot with the same pistol and a bullet of the same calibre, and at the same range. The area of smoke and grains was two inches in diameter; the skin was scorched in an area of half an inch, extending from the wound of entrance, which was lead stained; the number of grains imbedded was about the same as before, or possibly a little less, and not more than ten per cent. was removable by washing; no grains perforated the skin; and after washing no evidence of burn remained except an apparent slight loss of epidermis.

These and similar experiments show that the living skin is rather less penetrable by powder grains than the dead, and rather more susceptible to burn.

A reference was made by several of the medical witnesses to cases of contact wound, which they had seen in the living subject, as being confirmatory of their experimental observations. The pertinency of these cases is open to question; first, because there is no very particular reason to suppose that they were either observed or noted with the care which is essential to their value as evidence; second, because they could be classed as contact wounds only by inference founded upon certain changes in the structure and appearance of the parts which are assumed to be characteristic, the very point which it is sought to prove.

The solubility, to some extent at least, of powder or of the products of its more or less perfect combustion in blood as well as in aqueous fluids is so easily demonstrable that it would seem there could be no doubt about it; and what evidence there may be which could justify a statement either that it will dissolve in the brain in a specified time of ten minutes, or that no part of it will dissolve at all, it is impossible to conceive.

There are other matters of testimony which might well be questioned if their influence upon the result de-
manded or time permitted. Passing reference to a single one of these, however, should be made, as it involves a remarkable negation of an established chemical fact. It was asserted by the State that carbon is one of the products of the combustion of gunpowder, and charcoal deposits in the tissues were described as characteristic of certain experimental shots. As a matter of fact, carbon is not recognized by authoritative writers as a resulting product of such combustion. Noble and Abel * found it to exist in the solid residue only in potassium combinations, and its remainder in gaseous forms. Bruff and others, the highest authorities in ballistics, have arrived at practically the same results. Such inferences and contentions, therefore, as were founded upon this chemical error must be held to be without warrant.

The examination of the expert witnesses was prolix and minute to a degree which seems to have been unnecessary if it were simply intended to determine from experimental observations the range at which the wound in question was inflicted. Days were devoted to the exploitation and criticism of experimental results which were accepted as pertinent, though obtained by the use of substitutes for the human tissues to which these structures were utterly unlike. Much time was occupied in the consideration of certain minute differences possible in the conditions of experiment, while others which were inevitable and equally important were ignored. Trivial variations were unduly magnified, and the significance of facts was sometimes depreciated or obscured by much insistence upon an explanation of the manner of their production. Such errors in procedure and in the estimation of values naturally resulted from a lack of previous experience in this particular line of investigation, and to some extent perhaps from the nature of the professional training of the gentleman directly in charge of the work of experimentation. The rigid processes of chemical analysis which deal with infinitesimal and ultimate atoms, and which reach attenuated conclusions with mathematical precision, have no counterpart in the broader generalizations of surgical diagnosis, in which no elements are absolutely fixed, and in which at most the limits of variation alone can be made certain.

In this review of the medical evidence adduced in a protracted case it is believed that no point of considerable importance has been left uncovered. The conclusion seems to be inevitable that the effort of the prosecution to show that the wound was of necessity homicidal absolutely failed. It had to be proved that the conditions which the wound actually presented were such that it was not only improbable, but impossible, that they could have been produced at any range at which a suicidal shot could have been fired.

The reasons for this failure, which have been already incidentally stated, may be recapitulated and summarized as follows:

The repeated disturbances, ablations, and examinations to which the body was subjected had changed to an unknown extent the distinctive characters of the original lesions by which alone range can be estimated. The basis of the whole process of investigation was consequently defective.

The experimental observations made for the purpose of interpreting these lesions were in greater part upon substances dissimilar to the human body and in which the conditions of experimentation were not even approximately comparable; while the number made upon the cadaver and upon the human head, which alone were strictly relevant, was too small to justify the wide generalization which was required.

The deductions, made either directly or by implication, from these experiments were in many instances erroneous, as demonstrated by more extended experimentation.

The hypothetical question in which the medical evidence was presumably summarized, though it had been proved that suicide in this case was practicable at any range less than six inches and a half, was confined to the possibility of a contact shot; and in this question the singeing of the hair and the condition of the subcutaneous tissues, which are of vital importance, were ignored, so that as propounded the question was incapable of categorical answer.

No formal effort was made to prove that the shot was not fired at any intermediate range less than six inches and a half, which, conformably to a premise established by the prosecution, would have been equally compatible with a theory of suicide.

The assertion that the same results were obtained in every instance at a range from contact to four inches was not justified by the few observations made, and is fully controverted by an adequate number of experiments made not only with this calibre but with various other calibres of pistol.

No adequate or successful effort was made experimentally to reproduce the conditions which had been found to exist in and about the wound in question.

It is for these several reasons that the attempt to prove by expert medical evidence the necessarily homicidal character of the wound was not only unsuccessful, but did not even establish a probability that murder was done. It was proved, if anything was proved, that the range of shot was within that limit within which either murder or suicide is possible, and the case was left where this evidence began, dependent for its solution upon the history of circumstance.

The expert testimony, it is said, still served the legal purpose of the prosecution; the accused was convicted of murder, and largely upon these speculations founded upon an imperfect knowledge of the original lesions and supported by an inadequate and therefore misleading
series of experimental observations. Three circumstances seem to have contributed to the result: (1) the fact that erroneous statements or deductions were not fully controverted; (2) the fact, not peculiar to this case, that the value of technical evidence was beyond the comprehension of the jury; and (3) the fact that, while the expert witnesses for the State were unassailed, those of the defense were discredited by attacks both upon their personal honesty and upon their professional capacity. It is but proper to state that these attacks made upon the medical gentlemen who appeared for the defense were not justified by the nature of their testimony, or by any evidence introduced to impeach either their personal or their professional character.

In the course of the special experimental observations made in connection with the review of this case it became of interest to note at what range, if any, within the limit of six inches and a half the appearances presented corresponded with those of the wound in question. One hundred and twelve observations were made in which shots were fired at human heads with the Colt’s revolver of 0.30 calibre, of the same type and date of manufacture, and having the same measurements as the one with which the suicide or the alleged crime was committed. Eighty-six of these were practically complete, and twenty-six were confined to the further elucidation of facts which were regarded as most pertinent. All of the lesions to be interpreted were found to exist individually, or in combinations of two or more, in many instances and at various ranges from contact to five inches. In a single instance at a range of four inches they were all reproduced collectively in an experimental wound, and at this range generally the results attained were more conformable to the characters of the wound inflicted upon the head of the deceased than they were at any other. It is not claimed that the fatal shot was fired at that distance, but it may be held as proved from the subcutaneous conditions attested that it was not fired at contact; and from the burning of the hair, that the distance was not more than five inches. It is merely a presumption that the range was approximately four inches.

**Therapeutical Notes.**

**Canada Balsam in the Treatment of Cystitis.**—Messing (cited in the *Klinisch-therapeutische Wochen- schrift* for October 22d) recommends the following pills:

<table>
<thead>
<tr>
<th>B</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Canada balsam</td>
<td>300 grains</td>
<td></td>
</tr>
<tr>
<td>Calcined magnesia</td>
<td>405</td>
<td></td>
</tr>
<tr>
<td>Powdered soap</td>
<td>1 each</td>
<td>a sufficiency</td>
</tr>
<tr>
<td>Powdered benzoin</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

M., ft. massa in pil. No. c div.

S. From four to six pills daily.

**An Antiseptic Gargle.**—*Riforma medica* for September 4th ascribes the following to Escut:

<table>
<thead>
<tr>
<th>B</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Salol</td>
<td>15 grains</td>
<td></td>
</tr>
<tr>
<td>Alcohol at 90°</td>
<td>750</td>
<td>“</td>
</tr>
<tr>
<td>Glycerin,</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Boiled water</td>
<td>6,000</td>
<td>“</td>
</tr>
</tbody>
</table>

M.

**For Constipation.**—R. C. Fisher (Texas Medical News, August; Monthly Cyclopedia of Practical Medicine, October) says that in the treatment of habitual constipation the good derived from cascara sagrada will depend upon the mode of administration; if given as a cathartic and only when necessary to unload the bowel, it fails to accomplish the desired end; but when given in small doses for its tonic effect upon the lower bowel, a much better result may be expected. As the bile is always found deficient in constipation, it becomes necessary to combine some cholagogue with the cascara; the following preparation of corrosive sublimate, cascara sagrada, and strychnine is of value:

<table>
<thead>
<tr>
<th>B</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Corrosive sublimate</td>
<td>1½ grain</td>
<td></td>
</tr>
<tr>
<td>Sulphate of strychnine</td>
<td>1</td>
<td>“</td>
</tr>
<tr>
<td>Distilled water</td>
<td>1 ounce</td>
<td></td>
</tr>
<tr>
<td>Fluid extract of cascara sagrada</td>
<td>4 ounces</td>
<td></td>
</tr>
<tr>
<td>Glycerin</td>
<td>sufficient to make</td>
<td></td>
</tr>
</tbody>
</table>

M. S.: One teaspoonful, more or less, two or three times a day, to maintain one action from the bowels each day; an initial purgative should be given. The patient should be instructed to find the minimum amount necessary to produce one healthy stool each day and then continue this for some time. A certain time in each day must be selected for the evacuation of the bowels.

**For Flatulent Dyspepsia.**—*Riforma medica* for September 7th gives this prescription:

<table>
<thead>
<tr>
<th>B</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Pure fluoride of ammonium</td>
<td>15 grains</td>
<td></td>
</tr>
<tr>
<td>Distilled water</td>
<td>4,500</td>
<td>“</td>
</tr>
</tbody>
</table>

M. A tablespoonful after every meal.

**An Ointment for Alopecia Areata.**—The *Journal de médecine de Paris* for August 20th gives the following prescription as Balzer’s:

<table>
<thead>
<tr>
<th>B</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Mercury subsulphate</td>
<td>5 parts</td>
<td></td>
</tr>
<tr>
<td>Flowers of sulphur</td>
<td>4</td>
<td>“</td>
</tr>
<tr>
<td>Oil of cade</td>
<td>15</td>
<td>“</td>
</tr>
<tr>
<td>Vaseline</td>
<td>30</td>
<td>“</td>
</tr>
</tbody>
</table>

M. To be applied to the bald spots at bedtime.

**For Diabetes Mellitus.**—Dr. J. M. Allen (Journal of the American Medical Association, October 28th), in a paper read at the last meeting of the association, says that he has used the following combination with apparent benefit:

<table>
<thead>
<tr>
<th>B</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Cresylate</td>
<td>4 drop</td>
<td></td>
</tr>
<tr>
<td>Tincture of nux vomica</td>
<td>10 drops</td>
<td></td>
</tr>
<tr>
<td>Saw palmetto</td>
<td>1 drachm</td>
<td></td>
</tr>
</tbody>
</table>

M.

**The Treatment of Hypertrophied Tonsils.**—*Riforma medica* for September 4th recommends:

<table>
<thead>
<tr>

Abundant hot irrigations therewith to be employed morning and evening.
THE NEW YORK MEDICAL JOURNAL.
A Weekly Review of Medicine.
Published by D. APPLETON AND COMPANY.
Edited by FRANK P. FOSTER, M.D.

NEW YORK, SATURDAY, NOVEMBER 18, 1889.

CHINESE RINGWORM.

This is not a disease that prevails in this part of the world, so our home practitioners are not likely to come in contact with it, but, in view of our recent territorial requirements in the Pacific Ocean, some knowledge of it will be useful perhaps to physicians who may go to our new islands either in a military capacity or with a view to private practice. Although the disease is generally known as Chinese ringworm, it is called tokelau by the natives of the islands where it prevails. Manson has given it the name of tinea imbricata, and Turner that of herpes desquamans. It occurs about the Straits of Malacca and on the islands of the Malayan Archipelago, and is characterized by desquamation of the cuticle in the form of concentric flakes which present free edges toward the centre of the patch, while toward the circumference they are firmly attached. This description is taken from Dr. Edward B. Bronson’s contribution on the subject to Foster’s Encyclopedic Medical Dictionary. Dr. Bronson refers the reader for further information to the Medical Report of the Imperial Chinese Maritime Customs for 1879.

A medical officer of the French navy, Dr. Tribondeau, has made an exhaustive study of the disease (Archives de médecine navale, July; Lancet, September 16th), and is not inclined to class it as a tinea—that is, he does not regard the parasite as a trichophyton. He proposes for the organism the name lepidophyton (from λείπος, a fish scale, and φυτόν, a plant). It appears that chrysophanic acid is a sovereign remedy for the disease, as is thus set forth in a passage translated by the Lancet from Dr. Tribondeau’s article: “In 1889 a native who formed one of a group of Tahitians sent to the Universal Exhibition of Paris, being covered with squamous scales wished to take advantage of his sojourn in France by getting rid of his tokelau. He entered a hospital where they began the essay of a whole series of remedies without producing any permanent impression on the tenacious parasite. At last an ointment of chrysophanic acid brought it to reason. Returned to Tahiti, the patient gave the curative formula to an apothecary at Papeete. The ointment in every case acted like a charm, and if the disease still exists it is because the people affected are too lazy to submit to a complete destruction of the lepidophyton. It is, however, permissible to hope that in a few years tokelau will have become a disease of the past.”

ETHER VERSUS CHLOROFORM.

In few if any of the fields of therapeutics has more improvement been manifested during recent years than in the induction of anaesthesia, whether general or local. We have now at our command a multitude of anaesthetics, each reasonably safe if properly handled and each suited to meet some special requirement. Nevertheless, the old question of the comparative merits of ether and chloroform has still to be argued. Perhaps it will never be settled to everybody’s satisfaction until some anaesthetic is brought forward that shall prove as agreeable as chloroform and far less dangerous.

The genius of the late Sir James Y. Simpson, who introduced the use of chloroform, gave that agent such a vogue that, except in the United States, it soon came to be considered as the one agent to be used when anaesthesia was to be induced. By many persons, indeed, Simpson was believed to be the discoverer of anaesthesia itself. Chloroform, as everybody knows, is not at all disagreeable to take, while ether, administered unskilfully, is exceedingly unpleasant to all concerned. Deaths due to chloroform are not frequent, after all, and in rare instances death has been caused by ether. It can not be said, then, that ether is absolutely safe and chloroform extremely dangerous; we must never lose sight of the unquestionable fact that a state of profound anaesthesia, however induced, is dangerous in itself. This consideration, however, does not free us from the obligation to choose the safer of the two agents unless there is some special circumstance that makes it less suitable in a given case.

The art of giving ether properly should be more cultivated than it ever has been. True, the asphyxia and spasmodic rigidity of bygone times are now rarely witnessed, but the distressing sense of impending suffocation, the wild determination to break loose from the anaesthetist’s control, and the consequent waste of strength on the part of the patient and on that of those who have him in charge are still too frequently experienced. There are very few men who know how to give ether in such a way as to avoid its unpleasant action, but their number is growing, and it seems to be only a question of time when chloroform will be shorn of its superiority on the score of its rapid and easy induction of anaesthesia. In some of the hospitals of New York remarkably satisfactory results are achieved by begin-
EDITORIAL ARTICLES.

QUACKERY IN WEST VIRGINIA.

Although the State of West Virginia has a stringent law denying the right of practising medicine to all persons who have not a license as the result of passing the State examination, there are many quacks there who seek to evade the law on the plea that they are not practitioners of medicine. Prominent among them are the “osteopaths,” who profess to treat all diseases by manipulation, and claim immunity from the medical practice law on the ground that they do not write prescriptions, administer drugs, or perform surgical operations. Common sense gives the lie to their contention, and judicial decisions have done the same. The Clarksburg News cites the opinion of Judge Thompson, of Kentucky, who has defined the practice of medicine as the application or employment of “that branch of science which relates to the prevention, cure, or alleviation of diseases of the human body.” Moreover, the very statute which these “osteopaths” are defying includes “manipulation or other expedient” among the acts that constitute medical practice. It can not be granted that there is any reasonable ground for the contention that the practice of “osteopathy” is not the practice of medicine, and the same must be said of “Christian Science,” “faith-healing,” and all the other delusions under cover of which the harpies that prey upon the credulous seek to elude the requirements of the law.

We are glad to see that a committee on illegal medicine appointed a few months ago by the medical society of the State of West Virginia is performing its duty energetically. The committee consists of Dr. W. P. Goff (chairman), Dr. T. M. Hood, Dr. C. S. Hoffman, Dr. N. S. Myers, Dr. V. T. Churchman, Dr. T. L. Barber, Dr. W. H. Sharp, and Dr. T. A. Harris. On September 7th the committee authorized its chairman to send a circular letter to every physician in the State asking him to contribute a dollar to a fund for procuring counsel and meeting other expenses incident to enforcing the State medical laws. Chairman Goff informs his professional brethren that the physicians of West Virginia are making “a determined fight against all forms of quackery.” While they are not criticising any “system” of medicine, they are seeking to compel all practitioners of medicine to conform to the law. They properly insist that the employment of any agency purporting to prevent, cure, or alleviate disease constitutes medical practice, and they ask members of the profession in other States to furnish them with court decisions bearing directly or indirectly on the question of whether or not they are right in their contention from the legal point of view. Dr. Goff, who lives in Clarksburg, asks that, if practicable, such material be sent to him through the United States Express Company, and adds that he is willing to pay all expenses connected with procuring evidence of this character. We would urge all our readers to exert themselves to assist the physicians of West Virginia in their most commendable endeavor to purge the State of quackery, and we believe there is no better way of doing so than by furnishing Dr. Goff with the evidence he asks for.

MENTAL ALIENATION AND PHYSICAL AILMENTS.

As a set-off against the post-operative psychoses of which we have heard so much of late, comes a report by Mr. J. Paul Bush (Bristol Medical-chirurgical Journal, September) recording Some Unusual Operations on Lunatics, with their Results. The cases are five in number: Ingrowing toe nails, vesical calculus, uterine fibroid, peritoneal abscess consequent on perforating gastric ulcer, and the extraction of swallowed pins from the stomach. The special points in these case are: first, that the cases were consecutive and not picked; secondly, that the mental alienation was manifest in all the patients for months or years before the condition demanding surgical intervention was present; thirdly, mental improvement in each case began shortly after the operation, and this improvement continued till apparently the brain was restored to a healthy state, and so continued up to the date of writing. These cases differ from others recently reported by gynaecologists in which operative measure were followed by mental improvement, upon which cases they have based a recommendation for thorough pelvic examination in all cases of mental alienation in women, inasmuch as no relation of cause and effect is suggested between the physical and mental conditions. But one thing is certain, viz., that these three conditions—psychoses following and apparently determined by operative procedure in healthy patients, mental alienation seemingly consequent on physical conditions and removable with their removal, and the disappearance of preexisting psychoses immediately following operative procedures for apparently subsequent and unconnected physical ail-
PREPARATIONS MADE FROM BLOOD.

The idea of making use of blood or some element of the vital fluid as a reconstituent medicine commends itself naturally, as is shown by the old practice of drinking bullock's blood, but Dr. W. Rosenstein (Deutsche medicinische Wochenschrift, 1899, No. 17; Centralblatt für innere Medizin, October 14th) thinks that it rests on a false assumption, for it has not been shown that the iron of blood is absorbed from the stomach. Blood preparations can prove effective, he says, only when given by intravenous or subcutaneous injection, and neither of those methods of administration is suitable for general use.

A HYGIENIC CRUSADE AGAINST BUGS AND PLEAS.

The extermination of fleas and bugs in France is urged by the Gazette médicale de Paris (cited in the Province médicale for September 30th) on the ground that, on the authority of Dr. Simond, a medical officer of the navy, they are largely instrumental in spreading the plague. If the appearance of the plague on the frontier between France and Portugal leads to the wholesale destruction of these insects, the visitation will not have proved an unmitigated evil.

INTER-STATE RECIPROCITY CONCERNING THE LICENSE.

The Detroit movement in favor of reciprocity among the States in the matter of granting the license to practice medicine shows gratifying signs of activity. We learn that it has already been endorsed by the State medical societies of Vermont, Idaho, and Utah and by the Illinois State Board of Health. In their circulars the committee explain that they do not expect any examining board to lower its requirements. That, of course, is not to be thought of; adjustment must lie in a scaling upward, not downward.

A GIGANTIC LITERARY ENTERPRISE.

Some years ago Kuhn edited the works of a number of the best-known classical writers on medicine, in twenty or more huge volumes. That was properly regarded as a great undertaking, but it seems likely to be eclipsed by one now in progress in Greece under the direction of Dr. Phoustanos. We learn that this new edition will be in sixty volumes, that there are engaged in its preparation physicians of various parts of Europe, and that the editor expects to get American cooperation also.

THE FUNCTIONAL CAPACITY OF THE RETAINED TESTICLE.

Mr. B. Smith (Guy’s Hospital Reports, iii; Centralblatt für Chirurgie, October 21st) seems to have made considerable additions to our knowledge concerning the functional capacity of retained testicles, founded on a study of fifteen cases. He finds that before puberty the retained testicle not only is abnormally small, but shows signs of defective development in the size and number of the seminiferous tubules. Even at puberty such a testicle does not usually reach a normal development and has no functional capability. It is only in exceptional instances that it approximates the normal development. In one case, however, Mr. Smith found evidence of spermatogenesis. Even in the more favorable instances premature senile degeneration soon sets in. Nevertheless, for a short time after puberty cryptorchidism is not incompatible with procreative power.

“ASCITES OF THE LIVER.”

This is the cause assigned by one of the daily newspapers for the death of a city official. Perhaps the term, though probably not to be found in the books, is expressive enough.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported for the two weeks ending November 11, 1899:

The Medical Association of the Greater City of New York.—A stated meeting was held on Monday evening, the 15th inst., at which the following papers were presented for discussion: The Therapeutic Application of Carbonic-acid Gas, by Dr. Achilles Rose (discussion opened by Dr. W. Freudenthal with remarks on the use of carbonic-acid gas in diseases of the nose and throat); and Remarks on Symphysiotomy, with a report of three cases, by Dr. Thomas Rutherford Savage, which was discussed by Drs. C. G. Barrows, Dr. E. B. Cragin, Dr. A. F. Currier, Dr. Austin Flint, Jr., Dr. E. A. Tucker, and Dr. E. E. Tull.

The Medical Society of City Hospital Alumni, St. Louis.—At the last meeting, on Thursday evening, the 16th inst., the following papers were read: Some Remarks on Dementia Paralytica, by Dr. Edward C. Runge; The Boldness with which General Practitioners not Living in Large Cities perform Laparotomies, by Dr. Ralph A. Reder; and Observations on Certain Early Diagnostic Signs in Measles, by Dr. George Homan.

The Association of the Alumni of the New York Hospital will hold its next regular “smoker” in the administration building of the hospital on Monday evening, November 20th, at nine o’clock. Dr. D. B. St. John Roosa will read a paper on The History of the Hospital, and officers for the ensuing year will be elected.

The New York Infirmary for Women and Children, which, as our readers were informed some time ago, has
ceased to be a degree-giving institution, announces special courses for women graduates and undergraduates in medicine. Full information may be obtained by addressing the secretary, Miss Wilde, No. 321 East Fifteenth Street, New York.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending November 11, 1899:

**Small-pox—United States.**
- Chicago, Ill. .......... Oct. 27–Nov. 4 .... 1 case.
- Ottumwa, Iowa. ......... Oct. 1–7 ....... 1 case.
- New Orleans, La. ....... Oct. 27–Nov. 4 .... 1 case.
- New York, N. Y. ......... Oct. 27–Nov. 4 .... 1 death.
- Cleveland, Ohio. ......... Oct. 27–Nov. 4 .... 2 cases.
- Nashville, Tenn. ......... Oct. 27–Nov. 4 .... 1 case.
- Portsmouth, Va. ......... Oct. 27–Nov. 4 .... 1 case.

**Small-pox—Foreign.**
- Rio de Janeiro, Brazil. .... Sept. 30–Oct. 6 .... 70 cases, 58 deaths.
- Athens, Greece. .......... Sept. 7–14 ....... 7 " 2 "
- Bombay, India. .......... Sept. 26–Oct. 5 ....... 6 "
- Tamsui, Formosa, Japan. .... July 1–Aug. 31 .... 36 " 1 death.
- Chihuahua, Mexico. .... Oct. 21–28 ....... 3 cases.
- St. Petersburg, Russia. .... Oct. 7–14 ....... 4 " 1 "
- Warsaw, Russia. ......... Oct. 7–14 ....... 3 cases.
- Erzerum, Turkey. ......... Oct. 1–7 ....... 2 " 1 death.
- Snyrma, Turkey. ......... Oct. 8–15 ....... 1 "

**Yellow Fever—United States.**
- Key West, Fla. .......... Nov. 1–6 ....... 19 cases.
- Miami, Fla. .......... Oct. 31–Nov. 6 ....... 27 "
- New Orleans, La. ....... Oct. 28–Nov. 6 ....... 16 " 6 deaths.

**Yellow Fever—Foreign.**
- Rio de Janeiro, Brazil. .... Sept. 30–Oct. 6 .... 5 cases, 4 deaths.
- Havana, Cuba. .......... Oct. 19–26 ....... 24 " 4 "
- Vera Cruz, Mexico. .... Oct. 19–Nov. 2 ....... 6 "

**Cholera.**
- Bombay, India. .... Sept. 25–Oct. 3 ....... 2 deaths.
- Calcutta, India. .... Sept. 16–23 ....... 4 "
- Kurrachee, India. .... Sept. 23–30 ....... 1 case, 1 death.

**Plague.**
- French Ivory Coast, Africa. .... Sept. 16 ....... Recurrence.
- Magnilo, Lorenzo Marques, Africa. .... Sept. 11–18 ....... Recurrence.
- Bombay, India. .... Sept. 26–Oct. 30 ....... 95 cases.
- Calcutta, India. .... Sept. 16–23 ....... 47 "
- Kurrachee, India. .... Sept. 23–30 ....... 4 cases, 3 "
- Tamsui, Formosa, Japan. .... July 1–31 ....... 66 " 63 "
- Asuncion, Paraguay. .... Sept. 14 ....... Plague suspected. Has since been officially confirmed.

The Late Dr. Edward Bleecker, of Whitestone, New York.—At a special meeting of the Flushing Hospital staff, held on November 6th, the following minute was unanimously adopted:

In the sad Providence which has removed from among us our late associate we hasten to record this tribute of our esteem and affection as a meager memorial to his high character and sturdy manhood. Had Dr. Bleecker sustained no other relationships, his commanding position as a leader of men, his numerous and honorable official positions, and his wide sympathies with all that affected the people among whom his life was spent were enough to mark his career as aside and above that which falls to most men.

As his professional associates we add our hearty testimony to his varied and rare accomplishments as a physician. Removed at a time when all his powers were at the climax, wise in counsel, and always resourceful in expedient, he won our admiration and commanded our respect in emergencies where unfaltering courage could alone save life. To his untimely death brings a sense of irreparable loss only less than to those of his closest associates. To them we extend our deepest sympathy in a bereavement that, after all, only time can assuage and heal.

The St. Louis Medical Society.—At the last regular meeting, on Saturday evening, the 11th inst., Dr. J. B. Ross presented a paper in which he reported a case of adenocystoma hepatitis, with operation and recovery, and a case of polycystic degeneration of both kidneys.

The Buffalo Academy of Medicine.—At the last regular meeting of the Section in Medicine, on Tuesday evening, the 14th inst., the following papers were presented for discussion: Protracted Pneumonia and Slow Resolution, by Dr. John H. Pryor; and The Hygiene of the Asthmatic, by Dr. George N. Jack, of Depew, New York.

The New York Polyclinic.—We are informed that Dr. Morris Manges has been appointed professor of general medicine.

The Society of Medical Jurisprudence.—At the last regular meeting, on Monday evening, the 13th inst., Dr. Hugh Hamilton, of Harrisburg, Pennsylvania, presented a paper entitled The Medical-legal Autopsy; a Plea for Medical Precision and Legal Recognition.

Changes of Address.—Dr. J. F. Connors, to No. 117 West Eighty-third Street, New York; Dr. Evelyn Garigue, to No. 18 West One Hundred and Third Street, New York; Dr. J. B. Gerl, to No. 181 West Eighty-seventh Street, New York; Dr. Ernest L. Hicks, to No. 46 West Eighty-third Street, New York; Dr. R. S. Hindall, to No. 181–182 Seventh Avenue, New York; Dr. L. M. Hubby, to No. 40 West Eighty-fourth Street, New York; Dr. L. M. Hard, to No. 19 East Thirty-eighth Street, New York; Dr. L. M. Maduro, to No. 111 West One Hundred and Twenty-first Street, New York; Dr. William B. McCracken, to No. 329 South Broadway, Yonkers, New York; Dr. J. J. Morehead, to No. 54 West One Hundred and Fourth Street, New York; Dr. H. H. Rodman, to No. 2 West Eighty-eighth Street, New York; Dr. T. A. Smith, to No. 102 West Seventy-fifth Street, New York; Dr. George W. Talson, to No. 129 West Nineteenth Street, New York; Dr. J. S. Waters, to No. 48 East Eighty-third Street, New York; Dr. E. N. Wilcox, to No. 43 West Seventy-fifth Street, New York.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 4 to November 11, 1899:

BRADLEY, ALFRED E., Major and Surgeon, United States Volunteers (Captain and Assistant Surgeon, United States Army), having tendered his resignation, is honorably discharged.

COONEY, DANIEL C., Acting Assistant Surgeon, will report to the acting chief surgeon for duty in the office of the chief surgeon.

EBERT, R. G., Major and Acting Chief Surgeon of the Department, will proceed to Portland, Oregon, and make a thorough sanitary inspection of the United States transport "Lennox.

GREENLEAF, CHARLES R., Colonel and Assistant Surgeon-General, United States Army, will proceed to Manila for duty as chief surgeon of that department.
BUFFALO.

Infantry Station to Marine-Hospital to accompany that command to the Philippine Islands on the transport Meade.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Two Weeks ending November 12, 1899:

Bredhick, R. G., Passed Assistant Surgeon. Ordered to Washington for examination for retirement, and then home to await orders.

Costigan, G. D., Passed Assistant Surgeon. Promoted to passed assistant surgeon.

Eakins, O. M., Assistant Surgeon. Ordered to the Naval Academy.

Henerberger, L. G., Surgeon. Detached from the Indiana and ordered home to await orders.

Marmion, R. A., Medical Director. Promoted to medical director.

Norton, O. D., Surgeon. Detached from the Ranger and ordered to the Monadnock via the Solace.

Owll, H. E., Assistant Surgeon. Detached from the Naval Hospital, Mare Island, California, and ordered to the Ranger.

Simons, M. H., Medical Inspector. Promoted to medical inspector.

Smith, R. K., Passed Assistant Surgeon. Detached from the Naval Hospital, New York, and ordered to the Naval Hospital, Mare Island, California.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending November 9, 1899:

Cantor, H. R., Surgeon. To proceed to Miami, Florida, for special temporary duty.

Smith, A. C., Passed Assistant Surgeon. Relieved from temporary duty at the Tortugas Quarantine Station and directed to proceed on the steamer Powhatan to the Reddy Island Quarantine Station.

Nydegger, J. A., Passed Assistant Surgeon. To report at Washington for special temporary duty. Granted leave of absence for six days. To proceed to Cadiz, Spain, for duty.

Sprague, E. K., Passed Assistant Surgeon. Granted leave of absence for two days.

Greene, J. B., Assistant Surgeon. Granted leave of absence for twenty-one days.

Tabb, S. R., Assistant Surgeon. To rejoin station at Savannah, Georgia.

Anderson, J. F., Assistant Surgeon. Granted leave of absence for four days. To proceed to Barcelona, Spain, for duty.

Fricks, L. D., Assistant Surgeon. Relieved from special temporary duty at Key West, Florida, and directed to proceed to Miami, Florida, for temporary duty.

Schereschevsky, J. W., Assistant Surgeon. To report to Surgeon L. L. Williams, Immigration Service, New York, for assignment to duty.

Lord, C. E. D., Assistant Surgeon. To report to the medical officer in command, New York (Stapleton), for temporary duty and assignment to quarters.

GREGORY, G. A., Acting Assistant Surgeon. Granted leave of absence for five days.

Moncure, J. A., Acting Assistant Surgeon. Granted leave of absence for thirty days from November 15th.

Goodman, F. S., Hospital Steward. Granted leave of absence for thirty days from December 1st.

Promotion.

Greene, J. B., Assistant Surgeon, commissioned as passed assistant surgeon.

Appointments.

Schereschevsky, Joseph W., of Massachusetts, and Lord, Charles E. D., of Maine, commissioned as assistant surgeons.

Society Meetings for the Coming Week:

Monday, November 20th: New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Hartford, Connecticut, Medical Society; Chicago Medical Society.

Tuesday, November 21st: New York Academy of Medicine (Section in General Medicine); Buffalo Academy of Medicine (Section in Pathology); Ogdensburg, New York, Medical Association; Syracuse, New York, Academy of Medicine; Medical Societies of the Counties of Chemung (quarterly), Kings, Livingston (quarterly), and Westchester (quarterly), New York; Baltimore Academy of Medicine.

Wednesday, November 22nd: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Philadelphia County Medical Society.

MALARIAL AND TYPHOID FEVERS.

42 West Thirty-seventh Street, November 4, 1899.

To the Editor of the New York Medical Journal:

SIR: In your issue of to-day an article appears from the pen of Dr. William Osler, of Baltimore, entitled The Diagnosis of Typhoid Fever. In it I find the following reference to myself: "I have been scolded as too shockingy dogmatic on the subject, as some of you may remember, in a paper read a year or so ago by my friend, Dr. Beverley Robinson, but I protest that, dogmatic as I have been, I have not been dogmatic enough. Had we teachers throughout the country been more persistently dogmatic, the profession might have been spared the mortifying exhibition of last year. But, as for so many of us, so for Dr. Robinson, there is no possible satisfaction in this respect until born again of the microscope and a prolonged course of study of the genuine disease." Following this, Dr. Osler writes: "Two clinical rules should guide practitioners above Mason and Dixon's line: 1. An intermittent fever which resists quinine is not of malarial origin. 2. In these localities a continued fever is not due to malarial infection." I dissent formally from both these propositions laid down in this absolute manner. The reading again carefully of my paper in the New York Medical Record, January 15, 1898, pp. 75-77, will show the proofs of my position. I beg leave to inform Dr. Osler, as I have tried to do already, that I have had the kind service of several thoroughly competent microscopic experts in my clinical observations. I do not, therefore, consider it essential to be "born again of the microscope" so as to establish my rights to hold conservative and, I believe, correct views. "In medio satisimum ibis!"

BEVERLEY ROBINSON, M. D.

CHLORETONE AS A HYPNOTIC AND ANESTHETIC.

Detroit, November 3, 1899.

To the Editor of the New York Medical Journal:

SIR: We would respectfully direct your attention to an erroneous statement in the editorial which appears on page 631 of the New York Medical Journal for October 28, 1899, Chloretone as a Hypnotic and Anesthetic. We refer to the last sentence in the second paragraph, as follows: "Like all other drugs of its class, it is not devoid of dangerous properties; excessive doses prove fatal."

We would respectfully urge that this quoted statement is an injustice to us and to our product, since one of its particular merits resides in the fact that chloretone exerts no depressing action on the heart and that it is indeed wholly "devoid of dangerous properties."

We suppose that it would be possible to give a man enough chloretone to kill him, but we know of no authentic case in which the patient took one hundred and eight grains of chloretone—thirty-six tablets of three grains each—as a single dose. As a natural result, he slept for three days; for two days more he remained more or less under the influence of the drug; but his recovery was complete and he did not experience the slightest untoward effect. The physician whose patient took the enormous dose of chloretone is a reputable Detroit practitioner, and he sent a report of the case to the Therapeutic Gazette, where it will presently appear.

In our biological department we have given to dogs from 0.2 to 0.25 gramme per kilo, of body weight, keeping the animal under the influence of chloretone for several days and as long as a week at a time. The animal then emerges from the prolonged hypnotic without the slightest trace of untoward action, and subsequently appears to be in the best of health and spirits.

In the inclosed verbatim reprint of the paper contributed by Dr. Houghton and Dr. Aldrich to the Journal of the American Medical Association you will look in vain for the statement that chloretone "is not devoid of dangerous properties" or that its "excessive doses prove fatal."

We feel assured that no intentional injustice was done us, and we leave the matter in your hands for such correction as ought in fairness to be made.

Parke, Davis, & Co.
drug is administered, the animal remains completely insensible for several days, the respiration becomes slower and weaker, finally ceasing altogether, the sleep of anesthesia terminating in the sleep of death."

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL.B.

(Continued from page 719.)

Privileged Communications.

Privileged Matter Generally.—Upon the broad and urgent ground of public policy certain matters are held so sacred in the eyes of the law that one can not be compelled to disclose his knowledge relative thereto, even as a witness in a court of justice. Matters of this sort may be generally classified as follows:

I. Political Matters.—Under this head are included state secrets, official transactions and communications between the heads of departments of state and their subordinate officers, and all like communications.

II. Judicial Matters.—Herein are included proceedings in the jury room, consultations of judges, and the like.

III. Professional Communications.—Under this head are included all communications between client and counsel or attorney necessarily made for the purpose of securing professional services or assistance; communications between patient and physician or surgeon necessary to secure proper professional treatment; and all confessions or communications of like character made to one's spiritual adviser.

IV. Social Matters.—Under this head are included all communications of a confidential nature made between husband and wife.

Professional Communications at Common Law.—At common law the protection accorded to professional communications was in its scope very limited, applying only to the legal profession, nor does the protection which that profession enjoyed seem to have been as full and adequate as that now accorded to it by the courts and legislatures. The medical and clerical professions were both outside of the protection of the common law, both of England and the United States, and whatever privileges of protected professional confidence they now enjoy are expressly conferred by statute.

Statutory Protection to Communications between Physician and Patient.—In recognition of the importance of a full and absolute confidence existing between physician and patient in all matters of professional intercourse, the legislatures of about half the States * have passed wholesome laws which in effect assure the patient that the information necessarily imparted to secure proper and legitimate medical treatment shall not be wrested from the physician to whom he confided it, even in behalf of justice. The wording of the statutes upon the subject, as enacted by the several States, varies considerably; in New York, which was probably one of the first States to recognize the need of this sort of protection to the physician and patient by legislative enactment, the law in force provides that:

"A person duly authorized to practise physic or surgery shall not be allowed to disclose any information which he acquired in attending a patient in a professional capacity, and which was necessary to enable him to act in that capacity." *

The restraining clause that the "physician or surgeon shall not be allowed to disclose any information, etc," is reenacted almost verbatim in the States of Iowa, Michigan, Pennsylvania, and Nebraska; the majority of the States having statutes upon the subject impose practically the same restriction by using the expression that the physician "shall not (or can not) be examined," † or "shall not be a witness," ‡ or "shall not testify." The statutes of five States, to wit, Indiana, Kansas, Missouri, and Oklahoma, provide that a physician shall not be competent to testify as to information professionally obtained, while the statutes of three States, to wit, Arkansas, North Carolina, and Wisconsin, provide that the physician "shall not be required (or compelled) to testify." The statutes in several States expressly restrict the application of the protection to civil cases. Whether the protection of the statute in the absence of this restriction extends to criminal cases is a question which has been the subject of judicial decisions, which will be examined in their proper order.

The statute of North Carolina is subject to the provision that "the presiding judge of a superior court may compel such disclosure (of knowledge professionally obtained), if in his opinion the same is necessary to a proper administration of justice."

The privilege conferred by these statutes is primarily for the benefit of the patient, and he, therefore, either by his acts or by express consent, may waive the privilege and allow the physician to testify. By the statutes of several States it is expressly provided that the privilege is waived whenever the patient voluntarily testifies regarding the subject matter of the same. The question of what acts shall in the absence of express statutory provision be considered a waiver of the privilege has been passed upon in a number of cases.

Communications with Unlicensed Physicians not Protected.—The statute usually provides that communications shall be protected when made to persons "duly authorized to practise," or to "licensed physicians or surgeons," or to "qualified physicians and surgeons." These statutes will therefore not protect communications of a confidential nature made to one not legally qualified to practise medicine, but who is exercising the functions of a physician; such a person, upon

† California, Colorado, Idaho, Minnesota, Nevada, North Dakota, Oregon, Utah, and Washington.
‡ Montana and Ohio and Wyoming.
[] The restriction to civil cases exists in California, Idaho, Minnesota, Montana, Oregon, Pennsylvania, Utah, and Washington.
^ Kansas, Nevada, Ohio, Oklahoma, and Wyoming.
being called as a witness, may be required to disclose all information that he has gained from a patient, and the patient’s protest will avail nothing.*

(To be continued.)

Pith of Current Literature.

What not to do in Acute Conjunctivitis.—Dr. Edward Jackson (Denver Medical Times, October) thus describes the things that should not be done:

First. A mydriatic should not be used for acute conjunctivitis. It is to be feared that in the domain of ocular inflammations too many physicians have imitated the celebrated rule about leading trumps, thus: “When in doubt, prescribe atropine.” It is sometimes proper to prescribe a mydriatic in a case of acute conjunctivitis, but only for some complication, not for the conjunctivitis. The practitioner who feels some doubt as to whether the case is one of simple conjunctivitis or whether there is not some inflammation of the cornea or iris may reason that the former will get well anyhow, and that if there is keratitis or iritis the atropine is indicated. But if one can decide exactly what is the condition present, he ought to bear in mind that it may be glaucoma, in which case the mydriatic might do serious permanent harm. A mydriatic, used in sufficient dose to be at all beneficial, is too powerful a drug to be resorted to except upon an exact diagnosis, and in conjunctivitis its influence is more likely to be harmful than beneficial. In a few susceptible patients, instillations of the ordinary mydriatic solutions produce violent outbreaks of conjunctivitis, with great swelling of the lids. More frequently they distinctly aggravate a pre-existing conjunctival inflammation. They always produce dilatation of the pupil, blurring of vision, and a desire to shun the light, and even the enforced rest for the eyes that they will secure will not compensate for their unfavorable effects.

Secondly. Do not prescribe cocaine in these diseases. It has no curative power, and the period of temporary relief during the anesthesia and contraction of the blood-vessels is followed by a period of increased vascularity and irritation. Cocaine may be used as a local anesthetic in acute conjunctivitis, to lessen the pain of strong astringent applications. Yet, even for this use, holocene is to be preferred. But if cocaine is added to a collyrium to be used by the patient, the temporary relief afforded is likely to lead to the frequent repetition of the application until very serious damage is done. Twelve years ago (Transactions of the College of Physicians of Philadelphia, June, 1887) the author reported a case in which sight was greatly damaged by opacity of the cornea under such treatment, and various other cases of harm from such a use of cocaine have been reported since. In some cases cocaine acts much like atropine, producing violent conjunctivitis.

Thirdly. Do not poultice the eye. There may be cases of ocular disease in which it is proper to use a poultice, but it is not proper in acute conjunctivitis. Sometimes, when one does not adopt a certain line of treatment, he never gets an opportunity to study its effects and revise his judgment. But it is not so in this case. The author has seen many eyes that have been poulticed for acute conjunctivitis, and every experience of the kind has left him more thoroughly satisfied that the eye was the worse for poulticing. It makes little difference of what the poultice is composed: scraped potato, raw oyster, bread and milk, flaxseed, corn mush, or tea leaves are about equally harmful. The latter article has been used so frequently that the “tea-leaf eye” is a well-recognized pathological entity. Its excessive, rather passive hyperemia, swollen lids, photophobia, and macerated appearance are generally easily distinguished, and the prescribing of a placebo with the poulticing of the poultice are certain to bring about prompt improvement. It would seem unnecessary to caution you against the poultice, were it not that the practice seems to have such a firm hold with the laity as to indicate that it must still be advised by some doctors, and occasionally some one, speaking even as an ophthalmologist, recommends the poultice in such a general and indefinite way that the advice might be taken as applying to acute conjunctivitis.

Fourthly. Do not bandage or use any sort of compress. The effect of a bandage of any kind is, to some extent, that of a poultice. The patient may regard the bandage as evidence of the surgeon’s care and the seriousness of the case. It may be important to impress the patient with the idea that you are doing all that can be done for him; but you should find some way of doing that without making the eye worse. Even in traumatic conjunctivitis, where rest is most important, the danger of infection overshadows all other dangers; and the bandage favors bacterial development so strongly that the culture test with it is recognized as the most searching practical test for pathogenic organisms in the conjunctiva. For similar reasons the compress is to be avoided. Even the ice compress, which is recommended by many authorities for gonorrheal conjunctivitis, the author would avoid. He has used it. He has watched its use by others who thought they saw great benefit from it; but he has not so interpreted the results. Even its enthusiastic advocates agree that it must be promptly discontinued when signs appear of corneal involvement, and corneal involvement is the thing to be dreaded in gonorrheal conjunctivitis. The cases without corneal involvement will get well anyhow, and the use of the ice compress does not tend to prevent it.

The author summarizes his entire paper as follows: 1. Acute conjunctivitis is not one but several diseases, the successful therapeutics of which rest on an exact diagnosis. 2. Possible eye strain should be considered in connection with every case not manifestly infective. 3. For all infective forms the most complete cleanliness of the conjunctival sac is the important measure. 4. Mydriatics or cocaine should not be prescribed for acute conjunctivitis. 5. To secure conjunctival cleanliness, all forms of poultice, bandage, and compresses are to be avoided.

Tumors of the Pituitary Body.—Dr. G. L. Walton and Dr. Cheney (Journal of Nervous and Mental Disease, August), in a paper read before the American Neurological Association, arrive at the following conclusions: 1. Congenital peculiarities in growth resembling those of acromegaly, but occurring in otherwise healthy individuals, may point to structural defect of the pituitary gland, a defect sometimes furnishing the starting point for new growth later in life. 2. The occurrence of pituitary tumor without definite symptoms
of acromegaly does not necessarily disprove a connection between this organ and this disease, for the persistence of even a small amount of healthy gland tissue is sufficient to carry on fairly the function of the pituitary body. 3. The combination of general symptoms of new growth with optic atrophy and loss of temporal field of vision makes the diagnosis of pituitary tumor almost certain. 4. Hemichromatopsia is not necessarily of central origin.

A Peculiar Case of Tetany.—Dr. F. Warren White (Boston Medical and Surgical Journal, November 2d) reports a case of tetany occurring in a boy three years and a half old in Boston. The features of special interest in this case were: 1. The limitation of the spontaneous contracture to the feet, which was rare, as the spasm almost always involved the hands, often the hands and feet at the same time. 2. The continuous character of the spasm, which was distinctly less common than the paroxysmal sort. 3. The short duration of the attack and the lack of any recurrence up to the present time, an interval of about two months.

"Functional" Heart Murmurs.—Dr. A. Jacobi (American Medical Quarterly, September) thus concludes a paper on this subject:

1. The diagnosis of deranged function in any organ is only a makeshift and is justifiable only so long as we are ignorant of the physical cause of that derangement. That heart murmur is called "functional" the anatomical cause of which we do not know. That is why a skilled diagnostician may recognize fewer functional murmurs than one who will not diagnose a heart disease unless he has all the symptoms, including dilatation and hypertrophy.

2. The same disorders of the blood and nervous system in which heart murmurs are observed in the adult do not cause them in the small infant. In the latter the heart is larger, more robust, and more powerful, and its contractions are more uniform and effective; its two ventricles are equally muscular, or nearly so, and the valves are smaller. Thus the greater frequency of murmurs in the adult is attributable to the physical condition of his heart, and should not be explained by a deranged function.

3. Even in the present limitation of our knowledge we should agree to call "functional" only those murmurs which are temporary, or intermittent, or variable in their character. They are met with in the neurotic and neurasthenic, in the (adult) anemic, sometimes in syphilitic or in chorea minor, and occasionally in rheumatism. Even here they should be recognized as myocardial or as neurotic.

Lenses for Both Far and Near Vision.—Dr. G. C. Harlan (Indiana Medical Journal, November) reminded the Section on Ophthalmology of the College of Physicians of Philadelphia that he had shown, about a year ago, a pair of bifocals made by Borsch in which the reading part was formed of a circular lens fifteen millimetres in diameter, made of flint glass and sunk into the distant lens, made of crown glass. The increased refraction of the small lens depended upon the higher index of flint glass, and its exposed surface was ground to the same curve as that of the larger lens. He had been in the habit of using these glasses in operating as well as in reading, and had found them entirely satisfactory. Recently Mr. Borsch had still further improved these lenses by burying the reading lens in the interior of the other, so that it was practically invisible. The large glass was split into halves, which were cemented together after the small one had been inserted between them. The glasses, which were exhibited, presented no indication of their method of construction, which was a veritable puzzle to the uninstructed. Dr. Thomson spoke in favor of the lenses, both from personal experience and that of his patients. He found that the position and shape of the small lens allowed one to walk, particularly up and down stairs, without difficulty.

Mechanical Support in the Treatment of Cardiac Asthma.—Dr. Abbe, of Bad Nauheim (Münchener medizinische Wochenschrift, 1899, No. 37; Deutsche Medizinal-Zeitung, October 16th), taking a hint from the instinctive manual pressure made on the cardiac region by patients on the access of a paroxysm, has contrived a pad to be worn over the apex, to give continuous support. It is attached to a belt.

Proceedings of Societies.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twenty-first Annual Congress, held in Chicago, Monday, Tuesday, and Wednesday, May 23, 24, and 25, 1899.

The President, Dr. William E. Casselberry, of Chicago, in the Chair.

(Continued from page 572.)

A Report of Two Cases of Accessory Thyroid Gland at the Base of the Tongue.—Dr. Arthur W. Watson read a paper with this title. (See page 579.)

A Case of Fibro-lipoma of the Tonsil, with Microscopic Section.—This paper was presented by Dr. Thomas Amory de Blois. (See page 622.)

Dr. John O. Roe, of Rochester: I recall a case of fibro-lipoma of the pharynx, a report of which I published three or four years ago, occurring in a woman about fifty-five years of age. It was a large tumor of about the size of a hen's egg and extended down behind the posterior wall of the pharynx, between it and the vertebral column, to a point opposite the arytenoid cartilages. It caused no ulceration nor breaking down of the tissues, but bulged forward so prominently that it very seriously interfered with deglutition. Liquids only could be swallowed with difficulty. I removed the tumor by making a vertical incision through the central wall of the pharynx, enucleating it, partly with the finger, partly with a slender curved instrument. The large cavity left after the removal of the growth was kept packed with gauze until it closed, and the patient made a rapid recovery. I had this tumor examined by an expert microscopist, who confirmed my diagnosis of fibro-lipoma.

The Relation of Pathological Conditions in the Ethmoid Region of the Nose and Asthma.

The Pathology.—This was the title of a paper by Dr. Henry L. Swain. (See page 613.)

Clinical Phases.—Dr. Clarence C. Rice presented this paper. (See page 694.)
Clinical Phases was the title of a paper by Dr. E. Fletcher Ingals. (See page 698.)

Treatment.—Dr. F. H. Bosworth read a paper on this subject. (See page 738.)

Dr. E. L. Shurly, of Detroit: On account of the complexity of the physiology of the vasomotor and ganglionic nervous system, I suppose it is almost impossible to settle exactly the etiology of asthma and hay fever. I was very much interested in Dr. Swain's paper, which I think is excellent. He presented the subject in a very concise and lucid manner. It seems to me that we should go further back than ethmoiditis or edematous rhinitis in considering the etiology and pathology of these cases. Recent researches have shown some strange anatomic and physiologic conditions of the nervous system that were never before dreamed of. One of the most striking things in connection with this subject is the fact that the diverse fine filaments or filings going from cranial nerves or spinal centres are carried together in the cables, so to speak, and in these little insulated cables there are found sensory, motor, and special filaments. It has also been discovered that in different animals, and in different individuals of the same race of animals, there is a great variation in the nature of communicating branches from the several nerve trunks. These anatomic variations, which we can scarcely call abnormal, may account in great measure for many cases of asthma and hay fever, aside from the ordinary physical results of local disease. It is easy to imagine changes in the nasal apparatus, and, by the way, the nasal apparatus has another function than that of respiration—namely, the function of olfaction. In civilized man olfaction is almost rudimentary, and if you study this region in the lower animals you will find it is a highly perfected complex apparatus. The arrangement of the olfactory blood-vessels and nerves is more direct in animals, while in man they are in a rudimentary state. Supposing we have a psychic or physo-psychic habit established—a tendency to the transmission of motor impulses along sensory filaments; supposing there be abnormal breaks in the insulation of these special nerve bundles, would it not account for a hyperesthesia or a paresthesia? The fact that some human individuals present this thing in marked form is rather confirmatory of the theory. We find some individuals who are analgetic, and others who are hyperesthetic. I suppose you have all seen so-called freaks whose mucous membranes and skin are entirely insensitive. I had the good fortune three years ago to have one of these freaks under my personal observation for three days. He allowed himself to be put through any sort of reasonable manipulation. I tested the different mucous membranes with all sorts of agents, and certainly the study of this man was quite edifying. You could thrust pins and needles through the skin and he would not feel them. Another strange thing was the effect upon the vasomotor system. We could open small vessels and the hemorrhage would be trifling; and yet this man otherwise was a healthy, muscular young fellow. He allowed us to open two or three superficial veins, and I was astonished to see so little hemorrhage from them. I had specimens of his blood examined, and no change from the normal could be found, excepting perhaps a slight increase of the so-called albumins. There were no changes found in the cellular elements of the blood; hence I concluded that all of the phenomena presented by this man were in a large measure neurotic. Now, from this point of view, must we not recognize two distinct classes of cases of asthma—those which may be due to local disease, as pointed out by Dr. Swain and Dr. Bosworth, such as edematous disease of the mucous membrane of the nose or an ethmoiditis, and another distinct class located on the psychic borders in which there are abnormal physiologic and anatomic conditions of the nerve distribution? The respiratory organs are very sensitive in such people. I have to differ a little bit with my friend, Dr. Bosworth, about the bronchial tubes being such negative or passive organs. He is willing to ascribe to the nasal passages respiratory functions of considerable importance. We have also important vascular and glandular systems in connection with the bronchial mucous membrane, and the adenoid tissue of the bronchial mucous membrane, which has not been studied much until of late years. It is quite as important an apparatus as the nose, and one which we ought not to continue to pass by lightly. The bronchial mucous membrane has its special regions of lymph nodes and nerve nodes. It has special nerve distributions and communications, and special epithelium, which, according to recent observations of physiologists, give importance to the trachea and bronchial tubes. The cilia differ from cilia of other parts distinctly in that they have a special function for aiding respiration and taking care of the secretion. Aside from this, there is another special function which belongs to the bronchial tubes—that is, the production of a secretion peculiarly fitted for reducing the friction of the air passing through them. The physiologic chemistry of the secretion of the trachea and of the bronchial tubes also differs materially from that of other mucous membranes. Therefore, I am inclined to think that it is quite as important, if only secondary, toward the performance of the function of respiration as that of the nose.

With reference to the remarks of Dr. Ingals, what he has said brought to mind the case of a friend and patient of mine who would have an attack of asthma from cats. I said to his brother-in-law that I thought it was mental. But he did not think his asthma was mental. However, to use a vernacular term, his brother-in-law and myself "put up a job on him." He was accustomed to go to his brother-in-law's on Sundays for dinner, and I said to his brother-in-law that we would get a couple of cats, give them an anodyne so that they would not mew, put them in a closet near the dining-room without his knowledge, and then see if John would have an attack of asthma. Accordingly, the cats were given a full dose of urethane and placed in the closet. The man with his wife and little girl went to dinner as usual, and soon John began to sniff, then to sneeze, and finally wheeze. He remarked to his sister-in-law, "Have you any cats here?" She replied, "You know very well that we do not keep any cats in the house." Finally, John was obliged to leave the table on account of excessive coryza, wheezing, etc. He had no knowledge whatever of the cats being in the house, and the animals were as quiet as mice on account of the drug which had been given them. This incident very forcibly corroborates what Dr. Ingals said of some people being subject to attacks of asthma after riding behind horses.

One more point, and then I am done. It must be obvious to all, especially those who have been engaged in general practice, that the majority of the cases of asthma are not accompanied by any sensible structural derangement of the nasal passages. When I say sensible derangement of the nose I mean this: Undoubtedly,
the nasal passages secrete more than may be considered normal in our northern climate. It is Nature's means of guarding the respiratory apparatus from cold air and the other changes due to our artificial mode of living. Too frequently we sit in a room heated at a temperature of 80° F., and then go out into a temperature of 32° or 40°. This sudden change produces changes in the vascular system, and I have come to regard a certain amount of asthma as a sort of physiological process established by Nature for the protection of the individual or the protection of the lower mucous membranes. We find a large number of these cases without any disease of the nasal passages that we can discover, and, of course, we must not go so far as to assume that because we do not discover any disease of the turbinate bodies, or of the outlying accessory cavities, that it must be there. I do not think that would be a fair argument or a rational way of thinking. The fact is being thrust upon us almost daily that there are persons of a neurotic type who are peculiarly sensitive; they are supersensitive. On the other hand, there are persons who are abnormally insensitive, and when we take into consideration recent biological and physiological discoveries relating to the nervous system, it seems clear that we have two distinct types of hay fever and asthma, the one depending entirely upon a peculiar condition of the nervous system, and the other depending upon a peculiar neurotic condition plus some local disturbance somewhere in the body.

Dr. J. N. Mackenzie, of Baltimore: This subject allows of the utmost latitude of discussion, and I shall only ask your attention to a few points that have come up during the reading of the papers. Dr. Swain's remarks agree in the main with the views which I have held upon this subject, and with which I have flooded the Transactions of this and other societies for the past sixteen years. I wish to call your special attention to a paper of mine, prepared and read before this association in Philadelphia in 1885, in which I covered in a very elaborate way the pathology of this class of diseases. I think one fact is established beyond the possibility of peradventure, and that is, that the primary cause of these affections does not reside in the nose, nor does it reside in any special peripheral organ, but lies in the individual himself. When we come to explain what the primary cause is, we enter the domain of the purest speculation, whatever may be the theories that have been advanced to account for it. The theory of so-called idiosyncrasy is possibly one of the most fashionable and the most convenient refuge of acknowledged ignorance. While we may acknowledge a vasomotor irritability, the fact remains beyond doubt that the primary cause of the trouble is as yet undiscovered. Dr. Swain's remarks support very forcibly the law which I laid down in the paper referred to, that the area in which the nerve explosion occurs will depend upon the seat of the local pathological process. In a neurothemic or hysterical individual a nasal polypus may induce attacks of asthma, a polypus in the rectum may create a disturbance of the lower bowel, and so on.

We have to speak in a general way of three classes: One, in which the primary irritation undoubtedly starts in some peripheral organ, which in our case is the nose. Another class of case may originate in some distant organ, as disease of the uterus or of the uterine appendages. Another class of case may originate in some systemic condition, as, for example, gout, rheumatism, and allied affections. The primal cause is, however, a matter of the purest speculation. I have sometimes thought that a localized hysteria might account for some cases of so-called reflex nasal neurosis that we meet with in practice. I do not believe in the theory of pressure contact. While in most cases there is present contact or pressure, as in cases of hypertrophy or edematous fibromata, in another class of cases, by no means very rare, the opposite condition prevails. In my original experiments on the subject of nasal cough, I made the statement that these reflexes rarely, if ever, occurred in cases in which there was atrophy of the nasal mucous membrane. I have since been compelled to change my opinion in that regard. I have not only seen it in cases of pronounced atrophy, but other cases have been reported by other observers.

Dr. Ingals's cases all point to one moral—that is, they point directly to the nervous apparatus as the essential factor in the evolution of this trouble. The explanation of these cases is not to be found in the so-called respiratory functions of the nose or of the bronchial tubes; we must go deeper than that. All the hypotheses which have been advanced on this line of reasoning are inadequate; they all fail to come up to the requirements of a logical hypothesis; all violate some one or more criteria. Asthma is more frequently a symptom of disease of the respiratory tract than any other tract of the body; but it is nevertheless a symptom, and it, and the vasomotor phenomena which we observe, are simply external signs, are simply outward and visible signs of something unknown within, which is, up to the present time, entirely beyond our ken. I can not fully agree with Dr. Bosworth that all polypoid degeneration is due to ethmoiditis. I do not base my opinion upon clinical observations alone, but upon pathological examinations made in this class of cases. I think we all agree with him as to the great importance of changes in the middle turbinate bone as establishing the presence of disease in the ethmoid cells. Ever since Grünwald called attention to changes in the ethmoid region as heralding the approach of disease deeper down, I think all of us who have had considerable experience have come to attest the value of his observations in that direction. I do not think intracellular pressure has anything to do with this class of cases. It is true, we have intracellular pressure in most cases of suppurrative ethmoiditis, yet only in a small proportion have we asthma and other reflex manifestations.

In regard to the treatment of ethmoiditis, when we find the disease firmly seated in that region, I partly agree with Dr. Bosworth, but I disagree with him as to the use of the forceps. I have never had any difficulty in the use of it even in operating on the deeper parts of the nasal passages. Also with regard to the gouge. I have operated with great facility, after the obstruction had been removed in front of the diseased cavity, with the gouge. In the last case of sphenoidal disease which I operated on I removed as much of the ethmoid structures as possible, when from the small orifice which led into the sphenoidal cavity there came a little cascade of pus. All in front had been cleaned out thoroughly, with the exception of this little space from which pus was discharging. I enlarged the opening with a burr drill, introduced a curette, and curetted the sinus out, and the last time I saw the man the probe went into the bony structures twelve centimetres, yet I had no difficulty in curetting the greater part of the sphenoidal
cavity. I think it is useless to temporize with curettage and other mild measures of the sort in the presence of extensive disease of the ethmoid cells; we have got to get the middle turbinate body out of the way. My method is to remove as much of the middle turbinate body as possible with the snare, depending, of course, upon the extent of the disease, and then clean out the remainder of the cavity with forceps and curettes. I agree with Dr. Bosworth in his estimate of the use of the drill; I am fond of it in intranasal surgery. We can polish off rough surfaces, we can make a cleaner job with the drill than with any other instrument at our command. I use the drill at the latter stage of the procedure, first removing the anterior end of the middle turbinate body, which is a simple thing to do with the snare, then removing the diseased portion as far as possible with cutting forceps and curettes, and polishing up and getting rid of the irregular surfaces left after forceps and curette work with the drill. So far, I have had no accidents, but the possibility of an accident should always be borne in mind.

Dr. G. Hudson Mauken, of Philadelphia: The discussion of this subject is most interesting to me, and it would seem that asthma, whatever may be its remote cause, depends directly upon a faulty neuromuscular action. This faulty action may depend on any one of a dozen different things. As has been shown, the remote cause may be in the presence of animals, such as cats, horses, or dogs; and their removal has prevented the manifestations of the disease; or it may be in intranasal pressure, because in some cases the removal of this pressure has cured the disease. The remote cause may be adenoid vegetations in the vault of the pharynx, for I have seen cases of long standing absolutely cured by their removal and the removal of the bronchial catarrh that has been the result of the adenoids. Asthma, it seems to me, has some analogy to the disease known as chorea and even stammering, if we may call that a disease, and the physician who treats these cases successfully is the one who can determine and remove the exciting cause of the faulty neuromuscular action.

Dr. Thomas Hubbard, of Toledo: Autoxemia undoubtedly plays a part in the causation of ethmoid disease and asthma. Its importance is underestimated. We have autoxemia of two general types, that which originates from the gastro-intestinal tract and that which is due to faulty elimination. The effect of the toxic influences of the different types of leukemias is exhibited by the vasomotor system and also diseases of mucous membranes through vicarious elimination. Ethmoid edema may be directly caused by lithemia, and persistent disease of this region may result. Systemic conditions must be constantly in mind in studying asthma even from the standpoint of laryngology.

Referring to the treatment, the fact that potassium iodide is of such usefulness in the treatment of asthma is one evidence that the practical way to attack this disease is by elimination, and that a study of autoxemia is the most practical way to reach the solution of the treatment of asthma. In my experience, local and operative treatment of certain disease conditions of the ethmoid and contiguous structures fails lamentably unless it be supplemented by systemic treatment of the kind that checks injudicious indulgence in heavy foods and stimulants, lessens suboxidation due to sedentari-ness, and increases elimination.

Dr. Swain: The question for discussion was the relation of pathological conditions in the ethmoid region of the nose and asthma, and in discussing the pathology I tried to confine myself to those considerations. Dr. Bosworth, in his remarks, leads one to suppose that he thinks every case of polypoid degeneration of the middle turbinate region is associated with what he calls “ethmoiditis.” From conversations I have had with other physicians, the majority of them are inclined to think that when the word ethmoiditis is employed, it means a purulent disease of the ethmoid cells, which Dr. Bosworth does not intend. If he believes that in all such cases there is disease of the bone and the cavities of the ethmoid, I wish to be a little at variance with him, because I know from actual microscopic examinations that such oedematous hypertrophies may exist for a long time on the outside of these thin trabeculae of bone which separate them from the cavities of the ethmoid, and the mucous membrane lining these cells may be absolutely healthy, as much so as any I have removed from known healthy subjects or have ever seen; consequently, it must be stated in plain terms that polypi can exist without the involvement of the ethmoid bones.

Dr. Shurly has touched upon a subject in which I have taken a great deal of interest, and seems to throw some light upon the actual disease which takes place inside the bronchial tubes, and this phase of the subject is of very great importance in considering the pathology. In examining pathological changes of the middle turbinate region among the first things we find to disappear are the ciliated extremities of the cells which cover the surface. Immediately after the cilia have disappeared the mucus tends to adhere. The cilia are necessary in order to expel the mucus, and give health to the surface. The same thing is true of the bronchial mucous membrane in a more marked degree. I have only a few data to substantiate these remarks, but in one or two asthmatic cases where I have examined the bronchial tubes they have lost their cilia over large areas. Such a condition must profoundly influence the ability to get rid of mucus from these areas, for the office of the cilia is essential in expediting the secretion from a lower to a higher level, and may account for the distressing difficulty these patients sometimes have in expostorating. Of course I am not unmindful of the dilating and stiffening of the tubes, which always accompany prolonged existence of the spasms of the asthmatics.

Dr. Bosworth: What I am about to say I say with a great deal of hesitation. I am a firm believer in clinical observation. The honored men of our profession from the time of Sydenham down to Trouseau, Flint, Loomis, and others of our day have taught us to base our facts to a certain extent on the study of disease at the bedside, rather than to be governed and directed by the deadhouse student, with his microscope. In saying this I do not deprec the use of the microscope, because it is a great aid in diagnosis. However, the microscopist sometimes tells us we are wrong when in carrying out certain clinical deductions, and certain treatment based on those clinical deductions, we know we are right in that our treatment is attended with success. With all due respect to the laboratory, I still hold up my voice for clinical observation. If ethmoid disease is not indicated by polypoid or oedematous degeneration, that peculiar condition of the middle turbinate body, and is not found after death by the microscope or by deadhouse observation, I question in my own mind if the student of the deadhouse has taken into consideration the post-mortem changes which occur in the mucous membrane. There
are certain changes in what we call vasomotor paresis in the mucous membrane which disappear at death. I will not give my clinical observation, which tells me that when I relieve intracerebral pressure by operating on the ethmoid cell it eures my case. The microscope tells me I am wrong, but my patient gets well from operative interference.

Dr. Casselberry: Will you be a little more explicit in describing to us the manner in which you use the burr—that is, using it as a probe first, then with downward pressure? It is the observance of little things that makes the method safe.

Dr. Bosworth: The advantage of the round burr is obvious in that you are able to grind off the walls and edges of the trabeculae. You grind for a while, then stop. You simply feel your way with the burr—you feel the edges and slowly cut further. You feel the little trabecular walls; you burr against them until they are off. You feel again, then burr six or eight seconds, and stop, and so on. Use the burr as a probe or investigator, go ahead, break down the trabecular walls, especially near the point where the burr enters, beneath the anterior part of the middle turbinated body. One great advantage in using the burr is that it serves as a guide to your operation. With care you can not do any harm if you go back into the nose further than to scrape a little mucous membrane off the septum. You are not likely to wound the ecriform plate. The thing to do is to work anteriorly and posteriorly in breaking down the cell walls.

(To be continued)

**BOOK NOTICES.**

**General Pathology, or the Science of the Causes, Nature, and Course of the Pathological Disturbances which Occur in the Living Subject.** By Dr. Ernst Ziegler, Professor of Pathological Anatomy and of General Pathology at the University of Freiburg in Breisgau. Translated from the Ninth Revised German Edition by Dr. Theodore Dunham, Dr. Edward M. Foote, Dr. Phillip H. His, Jr., Dr. Walter B. James, Dr. William G. Le Bouthillier, and Dr. Matthias Nicoll, Jr., of New York; Dr. B. Meade Bolton, of Philadelphia; Dr. Leonard Woolsey Bacon, Jr., Dr. John S. Ely, and Dr. R. A. McDonnell, of New Haven, Connecticut. Editor, Dr. Albert H. Buck, New York. New York: William Wood & Co., 1899. Pp. xxiii-598. [Price, $5.]

The translation into English of the author's recent extensive revision of his famous work places in the hands of English and American students and readers the material results secured by pathological research during the past five years. Besides many less important changes and additions to be noted throughout the volume, the revision has affected principally the chapters on retrograde disturbances of nutrition and on tumors. The results of many recent studies of the so-called hyaline degeneration have been recognized by the author, who has classified these processes in somewhat modified form and added much interesting and important detail to their consideration. While not fully accepting the conclusions of Czerny and of Krawkow on the relation of glyyogenic, hyaline, and amyloid deposits in tissues, the text relating to these subjects appears nevertheless to have been influenced by the results of these and other workers.

Apart from a minor change in the classification of tumors, the additions to this chapter consist principally in valuable discussions of the nature and origin of special growths. The limits of the class of endophylogiota have been extended, and many new illustrations of various neoplasms have been added.

Much recent work on pigmentation, inflammation, and the bacterial causes of disease has received attention in the chapters on these subjects.

The work as it now stands still maintains its original character as a finished text-book presenting the established facts of the science, while informing the reader of the present condition of our knowledge on controversial points. It may be true that such a volume overpowers the student unless he is carefully guided by the constant references to current discussion, yet this character of the work has always rendered it invaluable to the more advanced student and to the pathologist. Nevertheless, although this is the chief ground on which the work has maintained its prestige over other treatises, its value in this respect is again largely nullified by the omission of the bibliographical references of the German edition. The bulk of the volume can not stand as a sufficient excuse for this policy, since the German edition, with references included and with the text in larger type, weighs less than the American edition. The advanced student and specialist is therefore still unable to turn the American edition of the work to the best advantage. In all other respects the translation is most satisfactory.

**The Races of Europe: A Sociological Study (Lowell Institute Lectures).** By William Z. Ripley, Ph. D., Assistant Professor of Sociology, Massachusetts Institute of Technology, etc. Accompanied by a Supplementary Bibliography of the Anthropology and Ethnology of Europe, published by the Public Library of the City of Boston. New York: D. Appleton and Company, 1899. Pp. xxxii-624.

A Selected Bibliography of the Anthropology and Ethnology of Europe. By William Z. Ripley, Ph. D., Assistant Professor of Sociology, Massachusetts Institute of Technology, etc. A Supplement to The Races of Europe: A Sociological Study (Lowell Institute Lectures). Published by the Trustees of the Boston Public Library. New York: D. Appleton and Company, 1899. Pp. x-160.

It is hardly within the scope of this journal to give a comprehensive review of books of this character. But Dr. Ripley's work is in itself so interesting, and the subject is so closely allied with many medical questions, that we take pleasure in calling general medical attention to it. It is a study in European anthropology directed toward the environmental influences, rather than the purely hereditary ones, which have divided men into races. It includes the French, the Belgians, the Basques, the Teutons, and the Mediterranean and Alpine races; the races of the British Isles, the Russians, the Slavs, the Jews and Semites, the Greeks, the Turks, etc. These different peoples are individually studied as to their physical environment, their physical characteristics, and, to a certain extent, their social customs. In later chapters are considered their primary origins, the fac-
tor of environment versus race, the effects of climate, the influence of cities, etc.

The work is profusely illustrated with maps and photographs.

The Medical Complications, Accidents, and Sequelae of Typhoid or Enteric Fever. By Hobart Amory Hare, M. D., B. Sc., Professor of Therapeutics in the Jefferson Medical College of Philadelphia, etc. With a Special Chapter on the Mental Disturbances following Typhoid Fever. By F. X. Decem, M. D., Clinical Professor of Diseases of the Nervous System in the Jefferson Medical College, Philadelphia and New York: Lea Brothers & Co., 1899. Pp. vi-17 to 286. [Price, $2.40.]

The work before us is one of the most useful as well as one of the most readable works that we have been called upon to notice for some time. That its subject is important admits of no discussion, and, since typhoid fever is seldom in all respects typical, the book's advantages as compared with the necessarily limited chapters in the best of text-books and even "systems" of medicine are clear.

The work is comprised within seven chapters, of which the first is general in nature, discussing such matters as the prevalence, the mortality, and the age of commonest occurrence of the disease. The second chapter treats of the variations in its onset which, though scarcely to be classed as "complications," are certainly deserving of consideration in a volume like this. Aberrant Symptoms, States, or Complications of the Well-developed Stage of the Disease is the title of the third chapter and The Complications of the Period of Convalescence sufficiently describes the fourth. The fifth chapter is too brief. It deals with "conditions which ape typhoid fever." The subject is one deserving of more exhaustive treatment. The sixth chapter is also brief, and far too little is said of "second attacks." The volume ends with a chapter upon the mental complications of the disease.

We have thoroughly enjoyed this work; it is most important and most excellent. Its chief fault is that "in spots" it is too brief to satisfy, and we hope that a second edition will show an expansion in these places.

The fifth edition of this deservedly popular laboratory manual has recently appeared, following very shortly after the preceding revision. The present volume contains important additions to several chapters, particularly those on technics, disinfection, the specific infections, and immunity, embodying the important practical advances made in these subjects during the past two years. Many new illustrations appear, some of which are colored, and several sketches show variations in the morphology of some species as occurring on different media, and are very instructive. Nevertheless, the illustrations of the volume are still unsatisfactory, especially for students. The sketches showing the minute morphology of important species are still quite small and lacking in detail, while the woodcuts of gross cultures, though improved in some instances, remain inferior to the illustrations now appearing in some other similar works. Apparently the author does not accept the allegations of Sanarelli for the Bacillus tetani, and has not included this germ in the chapters on descriptive bacteriology. Considering the character of the work and the needs of students, for whom the volume is specially adapted, this and many other omissions are undoubtedly judicious. The constant feature of this work, namely, the concise statement of the elementary facts in the science, directed to undergraduate students of bacteriology, has been strictly maintained in the present edition, and will doubtless assure its continued use in the laboratory courses of most American medical schools.

In the third edition of this able work there has been some rearrangement of old material, and some new matter has been added. The most noticeable variation is in relation to the conditions that should modify the ordinary procedure of the Schott method. The work is an excellent setting forth of the Nauheim treatment.

The high opinion of this work expressed in these columns on the appearance of the first edition has been fully justified by its very favorable reception both here and abroad and by the prompt call for a second edition. The authors have improved the opportunity by rewriting some portions and by making numerous and important additions to the text throughout. We note such especially in the discussion of tuberculosis, tetanus, bubonic plague, yellow fever, malarial disease, and dysentery. The authors express considerable confidence in the statements of Sanarelli concerning the Bacillus tetani. The treatment of the subject of malaria is still unsatisfactory. The authors appear to be uncertain what classification to adopt, and unaware that the existence of a quotidian parasite has not been proved or accepted even by Marchi and Bigiani. The photographs of the malarial parasite and of the amoeba of dysentery are very clearly reproduced.

The short historical notes, a valuable feature of the work, have, in important subjects, been brought up to date. Many new photographic illustrations appear in this edition, all of which are good. Possibly the photographs of cultures have been excelled by those of some other recent works of the sort, but the general standard has, we believe, not been surpassed.
The volume probably contains more useful bacteriological information than any other volume of comparable size that has yet appeared in any language. It now meets more successfully than ever the requirements of a practical laboratory manual and short work of reference for students, physicians, and laboratory workers.

**BOOKS, ETC., RECEIVED.**

The Medical Treatment of Movable Kidney. By Alfred Stengel, M. D., of Philadelphia. [Reprinted from the University Medical Magazine.]

Neurasthenia. By John Punton, M. D., of Kansas City, Missouri. [Reprinted from the Medical-Index Lancet.]

On the Clinical Estimation of the Quantity of Haemoglobin in the Human Blood. By Thomas J. Jarrow, Jr., M. D., and Arthur P. Hitchens, M. D., of Philadelphia. [Reprinted from the University Medical Magazine.]

Gastropostis: A Report of a Case in which a New Operation was undertaken, and the Patient greatly Improved. By Alfred Stengel, M. D., and Henry D. Beyea, M. D., of Philadelphia. [Reprinted from the American Journal of the Medical Sciences.]

Bulletin of the Laboratory of Mount Hope Retreat. 1899.

**Miscellany.**

The Loomis Sanitarium Fire.—The physician in charge asks us to state that, although the administration building was totally destroyed by fire on October 14th, the work of the institution has gone on uninterrupted, the casino building having been temporarily adapted to the purposes of administration. It is expected that a new administration building will be completed within a few months. None of the patients’ cottages were at all injured by the fire.

The St. Louis Academy of Medical and Surgical Sciences held its annual meeting on November 7th, when the following officers were elected for the ensuing year: President, Dr. James Moores Ball; senior vice-president, Dr. William Porter; junior vice-president, Dr. H. G. Nichols; secretary, Dr. R. B. H. Gradwohl; treasurer, Dr. Emory Lanphere; orator, Dr. J. C. Murphy; curator and librarian, Dr. Robert Edward Wilson. Dr. Lanphere read a paper on Some Practical Points in the Treatment of Diseases of Women, and Dr. B. S. Simpson presented his thesis—Report of a Case of Exophthalmic Goitre treated by Sympathectomy.

According to the secretary’s report, the past year has been the most prosperous in the history of the academy. Twenty-three meetings were held, twelve pathologic specimens were presented, and forty-three theses and papers were read and discussed. The annual banquet was much enjoyed.

M. Bourneville’s Work with Feeble-minded Children.—Dr. L. Pierce Clark, of the Craig Colony, Son-ya, New York, has furnished us with the following remarks:

We are apt to give but little attention to researches on the feeble-minded and the mentally deficient, unless we are more or less immediately concerned with their care and treatment in special institutions. But the more recent work among this class is of particular interest because some of the best students have, by their studies of medico-pedagogies for the feeble-minded, already evolved practical results in improving educational methods for the normal child.

Volume xix of M. Bourneville’s Recherches cliniques et thérapeutiques sur l’épilepsie, l’hystérie et l’idiotie, just published, embracing the work of the year 1898, presents many points worthy of notice. The idea has been steadily growing of late years in educational circles that the backward child needs not only a little more care to place it ultimately on an equality with its fellows in obtaining an education. Bourneville has long been one of the chief exponents of this view. Again, every one must note with interest that each successive number of the yearly records of researches in the
Bicêtre proclaims a relatively decreasing number of the absolutelyunteachable idiots.

All the methods employed in sense instruction are very ingenious. Lessons are given in all the physiological processes—eating, breathing, walking, and the everyday care of the body. Many simple and effective methods are used for teaching the physical "characteristics and uses of things." Large and thoroughly equipped museums of objects assist the synthesis and analysis classes to provoke spontaneous, voluntary attention to become a persistent, concentrated one. Bourneville's reflections from year to year along this line are practical illustrations of Ribot's theoretical views upon the psychology of attention.

Many observations were made during the last year upon a typhoid-fever epidemic among the inmates of the Bicêtre, in which seven epileptics were included; in six of the seven epileptics no convulsions occurred during the fever, which is quite in accord with current investigations. Bourneville believes that the suspension of seizures in epileptics during febrile affections may be due to a vicarious manner that the nervous system has of spending its energy. However this may be, he states that in all his observations upon the association of typhoid fever and epilepsy the convulsions have always been retarded, even after convalescence from the fever, and in some cases he has seen an entire suspension of the epilepsy.

The yearbook presents a résumé of all previous statistical studies at the Bicêtre upon alcoholic parentage in the production of idiocy and epilepsy; such statistics in more than seventeen hundred cases, although confined to one nation, are overwhelming in their tendency to show that alcoholism plays an exceedingly prominent rôle in the causation of mental deficiency in children, and especially in the production of idiocy.

The clinical and pathological work done during 1898 in regard to idiocy, epilepsy, and hysteria in children, recorded in the nineteenth volume, equals that of previous years, if it does not surpass it, in careful, scientific character. Bourneville's great work in the Bicêtre is worthy of all praise.

Antikamnia Laxative Tablets.—The object of adding antikamnia to laxatives is not at first sight clearly apparent, but on inquiry we find that many physicians have for some time past frequently written magisterial prescriptions for laxative combinations with the addition of antikamnia—so frequently, indeed, as to have led the Antikamnia Chemical Company to prepare an antikamnia laxative tablet. It seems that antikamnia is considered an excellent carminative, and that accounts for the frequency with which physicians have prescribed it with laxatives.

A Chance Lost for a Christian-Science Cure.—Medicine for November, in its editorial comment on Dr. C. V. Comfort's snake cure for exophthalmic goitre, says that the course of exophthalmic goitre is subject to wide variations. Not long since the writer was consulted in a case of this kind, in which the patient had been under the care of a number of skilled physicians without benefit, and had received most of the approved methods of treatment. He was asked if Christian-Science treatment would do harm, to which he replied that it would probably do no harm, but that it was almost certain to do no good, and the patient left with the apparent intention of going to a Christian Scientist. Some months afterward this patient was seen and then seemed greatly improved in health and spirits. On questioning the patient the writer expected to hear a story of the wonderful efficacy of Christian Science in the treatment of this disorder, but was surprised to learn that the patient did not consult a "healer," for on the second day after the consultation she began to improve and continued to get better, so that she did not deem it necessary to consult any one. This was an example of the cases that improve without treatment.

The Thirteenth International Medical Congress.—The American national committee is constituted as follows: Dr. William Osler (chairman); Dr. George M. Sternberg, surgeon-general of the army; Dr. W. K. Van Beyden, surgeon-general of the navy; Dr. Walter Wyman, surgeon-general of the Marine-Hospital Service; Dr. W. W. Keen, president of the American Medical Association; Dr. H. P. Bowditch, president of the Congress of American Physicians and Surgeons; Dr. O. F. Wadsworth, president of the American Ophthalmological Association; Dr. H. G. Miller, president of the American Otological Society; Dr. E. D. Fisher, president of the American Neurological Association; Dr. G. J. Engelmann, president of the American Gynaecological Society; Dr. H. W. Stielwagon, president of the American Dermatological Association; Dr. Samuel Johnston, president of the American Laryngological Association; Dr. Robert F. Weir, president of the American Surgical Association; Dr. A. Jacobi, president of the American Climatological Association; Dr. E. G. Janeway, president of the Association of American Physicians; Dr. James Bell, president of the American Association of Genito-urinary Surgeons; Dr. H. M. Sherman, president of the American Orthopedic Association; Dr. R. H. Chittenden, president of the American Physiological Society; Dr. Burt G. Wilder, president of the Association of American Anatomists; Dr. Henry Kopluk, president of the American Pediatric Society; Dr. B. Holly Smith, president of the American Dental Association; and Dr. Henry Barton Jacobs (secretary, No. 3 West Franklin Street, Baltimore, to whom all communications should be addressed).

The meeting is to be held in Paris on August 2, 3, 4, 5, 6, 7, 8, and 9, 1900, under the presidency of M. Lannelongue. Membership will be granted to all doctors of medicine who fill out the application blank and return it, together with five dollars, to the secretary of their national committee. Physicians who wish to read papers at the congress will forward them to the secretary of the section in which they belong. The secretaries of sections are as follows: Comparative Anatomy, M. Auguste Pettit, No. 69 rue St.-André-des-Arts, Paris; Descriptive Anatomy, M. Rieffel, No. 7 rue de l'École de médecine, Paris; Histology and Embryology, M. Retterer and M. Loisel, No. 15 rue de l'École de médecine, Paris; Physiology and Biological Physics and Chemistry, M. Gley, No. 14 rue Monsieur-le-Prince, and M. Weiss, No. 20 avenue Jules-Janin, Paris; General and Experimental Pathology, M. Charrin, No. 11 avenue de l'Opéra, and M. Roger, No. 4 rue Petruait, Paris; Bacteriology and Parasitology, M. R. Blanchard, No. 236 boulevard St. Germain, Paris; Pathological Anatomy, M. Letulle, No. 7 rue de Magdebourg, Paris;

Clothing and Fashion.—We quote the following editorial from Medicine for November:

"One of the misfortunes of civilized man is that his raiment is prescribed by a changing and irresponsible fashion, that is dictated to a considerable extent by caprice, and perhaps still more by business considerations and financial necessities of tailors. Much criticism has been leveled at women's dress, tight lacing and high-heeled shoes having come in for not a little censure, and much has been written upon the twisted spines and 'corseted livers' which result from these follies. A further criticism of women's dress is that it is not sufficiently warm in winter, but the fact that this is offset by its being an admirably cool costume in the heat of summer is not generally stated. For the most part, the clothing of men is supposed to be quite sensible; it is, in the main, well adapted to cold weather, but during the hot season of the year it is altogether too heavy. In the fashioning of men's garments, the styles unfortunately come from a climate much cooler than our own. A weight of clothing which may be worn in comfort, and which, indeed, may be almost a necessity in the cool, moist atmosphere of England, is worn with the utmost discomfort in our own almost tropical summer temperature. Not only is the outer clothing too heavy, but the underwear is kept closely in contact with the body and vaporization prevented, and in addition starched collars and shirt fronts are worn, which likewise prevent evaporation and cause an immense amount of personal discomfort, not to say congestion of internal organs, and possibly diseased states. All this arises from the fact that we do not seem to have independence enough to dress according to the needs of our own climate, which requires an abundant supply of warm clothing in the winter, and a summer dress of thin, light, porous material.

"An example was noted on the golf links during the past summer. In many instances the golfing suits were composed of thick woolens, including a heavy vest, and in a number of cases a flannel shirt. These were reinforced by a heavy pair of worsted golf stockings, nearly a quarter of an inch in thickness. Of course, this was thoroughly Scotch, and if they had appeared on the links of St. Andrews they would have been strictly au fait. Unfortunately, as we have imported the game and costume in which it is played, we have not been able to import the temperature, which in the summer is very much below our average. In the few hot days which they have in Scotland golf is not generally played, and yet these days rarely exceed 80° or 85° F. The bulk of the golf-players in the other side of the water is done at a temperature ranging from 40° to 60° F, when leggings and heavy overgarments are a necessity. The same clothing worn upon our links, with the temperature running to 90° F. and above, becomes a simple absurdity.

"Undoubtedly much of the discomfort of our summers is due to unsuitable clothing. Any one who will try the matter will, we are sure, be convinced of this fact. A considerable degree of activity may be displayed if the clothing is suitable and admits of ready transpiration. There is a fallacy that underwear absorbs the perspiration. So it does, but in so doing it remains moist, and if covered by an outer garment acts as a poultice to the skin. The best dress for men during the extremely hot days of summer is a pair of light flannel trousers and a light linen or woolen shirt, with no underwear."

The New York Academy of Medicine.—At the last regular meeting, on Thursday evening, the 16th inst., Dr. Lewis S. Pilcher presented a paper on The Surgery of the Kidney.

At the next meeting of the Section in Ophthalmology and Otology, on Monday evening, the 20th inst., the following papers will be presented: Otitic Brain Abscess, by Dr. Emil Gruenig; Osteoma of the Auditory Canal, by Dr. Thomas R. Pooley; A Case of Suppuration of the Lateral Sinus and Thrombosis of the Interior Jugular with General Pyaemia, by Dr. Max Toepflitz; A Report of a Case of Removal of the Cochlea and a Part of the Semicircular and Facial Canals through the External Auditory Canal, by Dr. Robert C. Myles; The Indications for Ineundectomy during Operation for Acute Purulent Otitis Media and Mastoiditis, as a Prophylactic Measure against Subsequent Chronic Suppuration, by Dr. Frederick Whiting; and Ligation and Excision of the Internal Jugular Vein for Septic Thrombosis, by Dr. Edward B. Dench.

At the next meeting of the Section in Medicine, on Tuesday evening, the 21st inst., Dr. Henry W. Berg will read a paper entitled Diabète Bronzé and the Pathogenesis of Diabetes Mellitus, which will be discussed by Dr. W. H. Thomson, Dr. A. Jacobi, Dr. M. P. Meyer, Dr. M. Manges, Dr. Max Einhorn, Dr. J. Rudisch, Dr. N. E. Brill, and Dr. Alexander Lambert.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 22d inst., Dr. T. B. Berens will present a case of healed tuberculosis of the larynx, and Dr. Beaman Douglass will present a paper on A Study of the Application of the Galvanocautery in the Nose. New cases will be presented, and new instruments and specimens will be exhibited.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, the 23d inst., the following papers will be read: Nephrectomy for Ascending Tuberculosis, by Dr. Hiram N. Vineberg; Pregnancy complicated by Sarcoema of the Kidney, by Dr. Edward A. Byers; Atresia Vagina complicating Labor, by Dr. George Grey Ward, Jr.; and The Treatment of Cancer by its own Toxins, by Dr. P. J. McCourt.
FURTHER EXPERIMENTAL RESEARCHES ON THE EFFECTS OF DIFFERENT ANÆSTHETICS ON THE KIDNEYS.

By Robert Coleman Kemp, M.D.

(Continued from page 738.)

A. C. E. Mixture.—The anæsthetic known as the A. C. E. mixture is composed of alcohol, one part (by volume); chloroform, two parts; and sulphuric ether, three parts. This was tried by us on four dogs.

Carotid Tracings.—If it is administered by the open method, with ninety-five per cent. of air, the carotid tracings are wholly similar to those of chloroform; if by the semiclosed or closed, there is a very pronounced chloroform effect. This is clearly shown in the carotid tracings (Fig. 5) of a dog to which it was administered by the semiclosed method and but a moderate amount used for only a few seconds.

Kidney Tracings.—If this anæsthetic is administered by the open method, as above noted, with ninety-five per cent. of air, the kidney tracings are the same as those of chloroform: but when the semiclosed methods are used, the tracings immediately become like those characteristic of ether. As there is less ether, however, in the mixture, the kidney circulation, when the anæsthetic is suspended, recovers sooner than when pure ether is used.

The renal secretion is more copious than with pure ether, but less than with chloroform. When the A. C. E. is pushed the secretion is diminished, but never to actual suppression. Albumin likewise appears early, though not so early as with pure ether, but in larger quantity than with chloroform. The inference, therefore, seems legitimate that with this mixture the effects will be those of the inhalation of chloroform alone when the air is freely admitted, but that when the proportion of air inhaled is diminished by the semiclosed method, we then get the specific ether effect upon the kidneys, along with an increased chloroform effect upon the general circulation.

Schleich's Mixture.—Three solutions or mixtures are used by Schleich. No. 1: Chloroform, an ounce and a half; petroleum ether, half an ounce; sulphuric ether, six ounces. No. 2: Chloroform, an ounce and a half; petroleum ether, half an ounce; sulphuric ether, five ounces. No. 3: Chloroform, an ounce; petroleum ether, half an ounce; and sulphuric ether, two ounces and two thirds. All these solutions were employed with four dogs, with like results, differing only in degree.

The carotid tracings in the drawing (Fig. 6) show the effects of No. 3 solution, and are seen to correspond to those of the A. C. E. mixture and to be like those of chloroform.

The kidney tracings follow those of ether, or rather appear to occupy a position between those of pure ether and those of the A. C. E. mixture, being more pronouncedly like the ether effects than in the A. C. E. tracings. The recovery of the kidney circulation on the suspension of the anæsthetic took place rather sooner than from pure ether, but longer than after the A. C. E.

The renal secretion was diminished much more than with the A. C. E., though not quite to complete suppression. Albumin appears quite early, and with deep narcosis increases largely in amount, more than with A. C. E., but less than with pure ether.

In order to guard against error of interpretation of the oncometric tracings, as they might be in part affected by the movements of the diaphragm and of the abdominal viscera during respiration, altering the position of the kidney or the proper alignment of its pedicle, it was proposed to eliminate all such muscular effects by the use of curare. For this purpose several drops of a one-per-cent. solution of curare, or one or two drops of a three-per-cent. solution, were injected into the jugular vein. Artificial respiration was then resorted to every few minutes to keep up the action of the heart, but the respiratory movements were suspended, while the effects of the several anaesthetics were noted. In these observations no difference was noted from the respective effects of the different anaesthetics upon non-curarised dogs, except such as were due to the general depression of the circulation by the interference with the respiration. The ether, chloroform, A. C. E., and Schleich anaesthetics showed no variation from their previous results respectively, whether in the carotid or in the kidney tracings. Two dogs were used with such anaesthetics.

Nitrous Oxide.—This anaesthetic was administered during our experiments upon three dogs by Mr. Hasbrouck, who has a great experience in the use of nitrous oxide. Owing to the special effect upon the respiration by this agent, the general blood pressure is shown (in the drawing, Fig. 7) in the carotid tracings to be rapidly and markedly raised.

These results in appearance are closely parallel to those of asphyxia, and are accompanied by a good deal of struggling, and the excursions of the kymographic tracings are seen to be more pronounced than with any other anaesthetic. There is no depression of the heart until the respiration becomes much affected by pushing the narcosis, as was noted twice, when artificial respiration had to be resorted to. When this anaesthetic was suspended the heightened blood pressure fell to normal very rapidly, and quick recovery was noted when artificial respiration was employed.

Kidney Tracings.—These are rather peculiar in
Fig. 2: Osmometric and carotid tracings following the administration of A.C.E. mixture.
Fig. 6.—Onometric and carotid tracings following the administration of Schleich’s solution No. 3.
some of their features, but are explicable as dependent upon the kidney sharing in the effects of interference with the respiration and consequent general arterial contraction, as shown in the carotid tracings. Under moderate anaesthesia the onometric tracings at first fall, keeping close to and parallel with the base line. At this stage the onometric respiratory curves are very pronounced, while the vertical tracings—i.e., of the kidney pulse—are very short. If the anaesthetic is then pushed, the kidney waves disappear and the general tracing falls below the base line. These changes are very evanescent, and as soon as the anaesthetic is suspended the line rises again and the respiratory curves reappear, with a prompt return afterward to normal conditions.

The evidence, therefore, points to a contraction of the renal vessels corresponding in every particular with the general circulatory change, and not indicating any specific effect upon the kidneys.

Renal Secretion.—This is rapidly diminished, as might be expected from the fall in the kidney tracings. In complete narcosis some albumin appears, but it is moderate in amount, and soon disappears after the administration is suspended. A hypodermic injection of nitroglycerin is suggested in old people to diminish the tendency to high tension, or lessen the danger therefrom when employing nitrous oxide.

Anaesthol.—This anaesthetic mixture was recently devised by Dr. Willy Meyer as a substitute for Schleich's anaesthetic mixture. It is a combination of what he denominates M. S. and ethyl chloride.

M. S. is a solution of chloroform and ether in molecular proportions—i.e., 43.25 per cent. chloroform and 56.75 per cent. ether by volume. This, he states, has a boiling point of 52° C. or 125.6° F.

Ethyl chloride has a boiling point of 15° C. The proper proportion he states to be eighty-three per cent. of M. S. and seventeen per cent. of ethyl chloride by volume, and the boiling point of this solution is given as 40° C.

Its specific gravity he found to be 1.045; that of chloroform is 1.490, and, as on evaporating for five hours a thousand cubic centimetres of this solution at 40° C. he found the residue of twenty-two cubic centimetres to have a specific gravity of 1.262, he states that this fact shows plainly that to the last moment a solution of components discharges and not a final residue of chloroform." The report of Mr. J. C. Minor on M. S. and anaesthol (who also, as an expert chemist, investigated Schleich's anaesthetic mixture) will, we believe, effectually dispose of these claims. The reports are tabulated for your convenience.* We thus

* Solutions known as M. S. and Anaesthol. Chemical Tests by Mr. J. C. Minor, Jr.—Mr. Minor furnished us with the following reports:

M. S.—Dr. Willy Meyer calls by the term M. S. a solution of chloroform and ether in molecular proportions—i.e., 43.25 per cent. chloroform and 56.75 per cent. sulphuric ether by volume. This, he states, has a boiling point of 52° C. or 125.6° F.

I took 200 cubic centimetres of this molecular solution, prepared by Squibb, and proceeded to ascertain whether, as Dr. Meyer claims, such a solution would have a constant, or approximately constant, boiling point, thereby indicating that at any given time the proportions of chloroform and ether in the vapors were approximately the same as in that part of the solution not yet vaporized, or whether its boiling point would be an inconsistent and changing factor, indicating a variation between the proportions of the components of the vapors and of the remaining solution, and also between successive portions of the vapors. In the distilling flask the following was noted, 200 cubic centimetres being taken:

<table>
<thead>
<tr>
<th>Boiling Point</th>
<th>C.</th>
<th>F.</th>
</tr>
</thead>
<tbody>
<tr>
<td>60</td>
<td></td>
<td></td>
</tr>
<tr>
<td>60</td>
<td>212</td>
<td>123.5</td>
</tr>
<tr>
<td>55</td>
<td>185</td>
<td>123.6</td>
</tr>
<tr>
<td>45</td>
<td>162</td>
<td>134.6</td>
</tr>
</tbody>
</table>

These results certainly afford no justification for a statement that 52° C. is the boiling point of the solution M. S., and they plainly show that each of the four successive portions of the distillate contain chloroform and ether in widely differing proportions.

Anaesthol.—Dr. Meyer was not satisfied, however, with M. S., deeming its boiling point too high, and he therefore decided to add to it ethyl chloride, having a boiling point of 18° C. The proper proportion he states to be 88 per cent. of M. S. and 12 per cent. of ethyl chloride by volume, the boiling point of the resulting solution being given as 40° C.

The specific gravity he found to be 1.045 (that of chloroform is 1.490), and, as on evaporating for five hours 1,000 cubic centimetres of this solution at 40° C. he found the residue of 22 cubic centimetres to have a specific gravity of 1.262, he states that this fact shows plainly that "up to the last moment a solution of components discharges and not a final residue of chloroform."

The difference between the specific gravity of the residue and of the solution before evaporation may be said to also show plainly that the proportion between the components in solution (and therefore those in vaporous form) was widely different at different stages of the vaporization.

This is borne out by the following experiment: Two hundred cubic centimetres of the solution, containing ethyl chloride in the proportion above given (i.e., the anaesthol, or M. S. + ethyl chloride), were distilled during a period of four hours with the following results:

<table>
<thead>
<tr>
<th>Boiling Point</th>
<th>C.</th>
<th>F.</th>
</tr>
</thead>
<tbody>
<tr>
<td>17</td>
<td></td>
<td></td>
</tr>
<tr>
<td>17</td>
<td>212</td>
<td>123.5</td>
</tr>
<tr>
<td>15</td>
<td>198</td>
<td>123.4</td>
</tr>
<tr>
<td>50</td>
<td>162</td>
<td>134.6</td>
</tr>
<tr>
<td>50</td>
<td>162</td>
<td>134.6</td>
</tr>
</tbody>
</table>

It seems difficult to state, therefore, what the boiling point of this solution is, and grounds for saying that its boiling point is 40° C. certainly do not appear.

The boiling point rises from near that of the lowest boiling constituent to that of the highest, and constancy of the boiling point being indicative of constancy of composition, the variations of the boiling point of this solution show the marked and increasing variations in composition between the earlier and later portions of the vaporized solution.
Fig. 7.—Oncometric and carotid tracings following the administration of nitrous oxide.
had to be employed for twenty minutes before the anesthesia could be resumed, and during this period the heart’s action was hardly discernible. When the anesthetic was pushed there were tremors and convulsive twitchings of the lower extremities, associated with the respiratory symptoms. These tremors and twitchings and, lastly, the stertorous breathing and crying noises emitted by the animal when the anesthetic was first given by the mouth reminded one much of the effect of Schleich’s anesthetic mixture—the respiratory poisoning. We believe the element causing these symptoms to be the ethyl chloride. This, as stated by Ludwig, is an anesthetic, while benzine, an ingredient of Schleich’s mixture, has been clearly demonstrated by Meltzer not to possess anesthetic properties.

With anesthol we have (see Fig. 8)—

Carotid Tracings.—The depressing effect of chloroform is clearly demonstrated—in fact, an aggravated effect. By the open method the effect is of pure chloroform; by the semiclosed or closed method, it is more depressing than any of the anesthetics.

Kidney Tracings.—By the open method, ninety-five per cent. of air, the kidney tracings are the same as with chloroform. By the semiclosed or closed method the tracings are characteristic of ether; possibly the animal recovers slightly quicker when the anesthetic is suspended.

Renal Secretion.—Absolutely no secretion was procurable after the use of anesthol was begun. At the close of the experiment a few drops of extremely bloody

Fig. 8.—Onometric and carotid tracings following the administration of anesthol.
Fig. 9.—Demonstrates tracings following the administration of anesthols. Respiratory, carotid, and onometric tracings. No secretion of urine occurred after commencement of anesthesia, hence no drops registered. 1. Chloroform heart—severe. 2. Ether kidney—severe. 3. Respiration—toxic effect due to ethyl chloride, as demonstrated in text.
albuminous urine were procurable in the urer cannula. Great care was taken in obtaining this, and it was traced directly to the pelvis of the kidney. In spite of the renal circulation recovering possibly a fraction more rapidly than with ether, at no time was urine noted to drop from the cannula, and there was evident-ly a severe specific effect on the renal secretion.

We were inclined to impute this aggravated effect to the ethyl chloride. Fig. 9 shows both the respiratory and cardiac depression, and also the effects of ether on the kidneys. The respiratory effects are clearly demonstrated. Note the absence of urine drops. 

(To be concluded.)

REPORT OF CASES OF SUDDEN DEATH FROM PULMONARY EMBOLISM FOLLOWING INJURIES OR OPERATIONS IN THE PELVIC REGION.

By GEORGE P. BIGGS, M.D.

Sudden death from pulmonary embolism is often so entirely unexpected, owing to absence of premonitory signs or symptoms, that it is important to know the conditions which may precede such a complication. I present to you very briefly a report of five cases, selected from the records of the last three hundred and fifty autopsies at the New York Hospital, in all of which embolism was secondary to injury or operation in the pelvic region:

CASE I. Intracapsular Fracture of Femur; Thrombosis of Iliac Veins; Pulmonary Embolism.—J. P., aged eighty-two years, United States. History of a fall, striking on his left hip, causing intracapsular fracture of the femur. A splint was applied and the patient kept in bed. He was apparently doing well when, on the sixth day, he walked to the lavatory, and was there seized with severe dyspnea. With help he returned to his bed and there died of respiratory failure in about five minutes.

Autopsy.—The fractured femur showed but slight evidence of repair. The pulmonary artery going to the right lower lobe was completely filled with dark-red ante-mortem coagula, which were not adherent to the vessel wall. Similar loosely adherent thrombi nearly filled the left common and internal iliac and the right internal iliac veins. On the left side the thrombus had a rounded end, but on the right side it was ragged, as if portions had broken away.

CASE II. Dislocation of the Hip; Fractures of Ribs and Pelvis; Thrombosis of Iliac Veins; Pulmonary Embolism.—J. G., aged thirty-six years, United States, clerk. Patient was struck on the back by a falling barrel, which caused fracture of several ribs on the right side and dislocation of the left hip. His condition was serious at first, but after five weeks of gradual improvement there was every reason to expect recovery. Improvement steadily continued for another week, when he had a violent chill, followed by cold perspiration, cold extremities, cyanosis, irregular heart action, and death within a few minutes.

Autopsy showed that the immediate cause of death was occlusion of the left branch of the pulmonary artery and its main branches by red and mixed thrombi, which were originally molded in veins about the size of the iliacs. Similar thrombi were found in the left internal iliac vein and its branches, but the other pelvic veins were free from thrombi. Partially repaired fractures of the left acetabulum, spine of the left ischium, and the second, third, fourth, fifth, and sixth ribs of the right side were found.

CASE III. Operation for Inguinal Hernia and Hydrocele; Thrombosis of the Femoral and Iliac Veins; Pulmonary Embolism.—A. F. J., aged sixty years, Ireland, porter. History of hydrocele and irreducible her-nia. The sac of each was dissected out and removed. Patient was doing very well, when, on the fifth day after operation, he suddenly died after an attack of violent dyspnea.

Autopsy.—The wound was in good condition. Both branches of the pulmonary artery were packed full of non-adherent thrombi, chiefly of the red variety, but in parts mixed. When straightened out the thrombus in the left pulmonary artery was thirty-five centimetres in length and three fourths to a centimetre in diameter. Judging from its size, it must have formed in a femoral vein. It was folded upon itself several times as a result of blood pressure from behind. The thrombus in the right pulmonary artery was folded once upon itself, and its larger size would indicate formation in the inferior vena cava or a common iliac vein. It measured twenty centimetres in length and half a centimetre in thickness. Lying free in the inferior vena cava and common iliac vein was a third thrombus, twenty-two centimetres long and a half to three quarters of a centimetre in diameter, probably formed in the femoral vein.

CASE IV. Appendicitis with Perforation; Embolism of the Pulmonary Artery.—R. O., aged eighteen years, United States, clerk. History of acute appendicitis for two days. At operation a pocket of pus was found about the perforated appendix. Convalescence was prompt, and on the seventh day temperature, pulse, and respira-tion were perfectly normal. Death occurred suddenly on the eighth day.

Autopsy showed both branches of the pulmonary artery filled with red ante-mortem thrombi, which were originally formed in vessels of smaller size, probably the iliac veins. No additional thrombi could be found anywhere in the body.

CASE V. Suprapubic Cystotomy for Vesical Calculus; Pulmonary Embolism.—G. W., aged sixty-three years, United States, barber. The patient did particularly well after the operation, and had been told that he could go home the following week. On the tenth day after the operation he suddenly developed marked dyspnea and severe precordial pain and distress. Death resulted in about twenty minutes.

At autopsy the pulmonary artery and its main branches were found to be packed full of soft, red, ante-mortem coagula, which were not adherent to the vessel walls. A similar coagulum five centimetres long was found free in the inferior vena cava. The diam-eter of all these coagula suggested their probable forma-tion in the iliac veins, but no thrombi could be found in these vessels.

* Read before the Society of Alumni of Bellevue Hospital, June 7, 1899.
These cases are reported chiefly with a view to calling attention to the importance of considering this not infrequent fatal complication when giving prognoses. In not one of these five cases were there any symptoms to suggest thrombosis of the pelvic veins. The conditions preceding the development of pulmonary embolism were such as to warrant a favorable prognosis in each case. It is this absence of symptoms of thrombosis, and the convalescent state of the patient usually existing prior to loosening of the thrombi, which often leads the physician into the embarrassing position of having his patient suddenly die soon after he has made a most favorable prognosis.

The most constant symptoms recorded in these cases were dyspnea and precordial pain and distress. In one case the first symptom was a violent chill, which was followed by cold perspiration, cold extremities, cyanosis, and irregular heart action. Death usually occurred so soon after the arrival of the physician that no detailed statement of symptoms could be made.

So important is it to make careful search in order not to overlook such emboli that I have been led to adopt a routine plan of carefully removing and examining the blood which flows into the pericardial sac after removal of the heart, and then examining the pulmonary artery. The reason for this is that large emboli are apt to fall out of the pulmonary artery when it is cut across, or later, when the lungs are raised for removal, and in this way they may be overlooked. I would strongly urge this method of examination in all cases of sudden death, particularly if preceded by dyspnea.

The following brief conclusions are drawn from a study of a number of cases, of which those reported are good examples:

I. The emboli are usually in the shape of cylinders, a little smaller than the lumen of the vein in which they form. Such cylinders often become folded several times upon themselves as they are forced into the branches of the pulmonary artery.

II. The thrombi formed in veins are chiefly of the red variety, though occasionally they are mixed. They may be quite firm and slightly stratified, though at times, to the untrained eye, they differ but little from post-mortem coagula.

III. Once started, thrombi in the veins tend to grow rather rapidly in the direction of the blood current.

IV. At the best, the thrombi are but loosely attached to the wall of the vein, and may separate completely, leaving no distinct mark to indicate the area of attachment, as was the condition in two of the cases reported.

V. A long, cylindrical thrombus may have but a very small base of attachment to one side of a vein, while the remainder of the thrombus floats free in the blood. This explains the absence of symptoms of venous obstruction.

VI. While infection may sometimes play an important part in the causation of these thrombi, such does not usually appear to be the case. It seems probable that simple extension of thrombi formed in smaller veins, which were damaged at the time of operation or injury, or by subsequent inflammation, will explain the occurrence of thrombi in the large neighboring veins. Slowness of venous circulation naturally favors this process.

PREGNANCY COMPLICATED BY UTERINE FIBROIDS.*

By HENRY C. COE, M.D.

Although much has been written on this subject, which forms a favorite theme for discussion before obstetrical societies, it is one that can never lose its interest for the general practitioner as well as for the specialist.

My attention has been particularly directed to the subject of fibroids complicating pregnancy from the fact that within the past week I saw in a small hospital in a neighboring city three cases in succession which illustrated three separate phases of this question. I, of course, do not feel at liberty to refer to them except in a general way, but I shall allude to them further on in connection with the indications for treatment.

The two points of interest with regard to what may be called the natural history of fibroid tumors of the gravid uterus are: How does pregnancy influence the growth and environment of the neoplasm, and what is the variation in the progress of pregnancy when complicated by such tumors? These are discussed in all text-books and monographs. As this is a purely clinical report, I shall merely cite a few cases bearing on these questions.

With regard to the first, it may be stated briefly that the rapidity of growth of a fibroid under the influence of pregnancy is in direct proportion to its more or less intimate relation to the uterus. Thus, a pedunculated subperitoneal growth may remain unchanged, while an interstitial tumor undergoes marked enlargement. On the other hand, a subserous fibro-myoma situated in the lower uterine segment, or displaced and impacted in the cul-de-sac, may increase in size simply from obstruction to its circulation. The position of the tumor is therefore of no little importance.

I have seen several cases of multiple subperitoneal fibroids in which the influence of pregnancy seemed to be negative.

The following is a good example:

I saw the patient, aged thirty-five years, in consultation, when she was about five months pregnant. She had been married ten or twelve years without conceiving, so that it was important that she should bear a liv-

* Read before the Society of Alumni of Bellevue Hospital, June 7, 1899.
ing child. Two fibro-myomata of the size of an orange were easily palpated at the fundus uteri, and a third, of the same size, in the anterior surface of the uterus, just above the junction of the lower and middle segments. As the uterus had already begun to rise above the pelvic brim, it was decided not to interfere with the pregnancy, which went on to full term, the patient being delivered of a living child after a normal course. A careful examination of the growths two months later showed no appreciable increase in their size, while the uterine cavity measured about three inches and a half.

In a recent case, seen in consultation at the beginning of the fifth month, the tumor (as large as a grape fruit) occupied the lower segment anteriorly and was apparently firmly impacted, so that doubt was felt as to the advisability of inducing labor on account of the obstruction, and abdominal hysterectomy was elected by the patient. Under anesthesia, two weeks later, the tumor was easily pushed up into the abdomen and pregnancy was allowed to continue.

In the following case, however, the outcome was not so fortunate:

The patient, aged forty-two years, was under my observation for nearly fourteen years. She attended one of my clinics for several years, having an extra-peritoneal fibroid, not larger than an English walnut, situated in the lower uterine segment and displacing the bladder anteriorly. I lost sight of her for three years, and then assisted at an explorative abdominal section performed upon her for hydromephrosis due to pressure of the growth on the ureter. Although the tumor was not disturbed, the manipulations during the operation resulted in the removal of the pressure and the disappearance of the hydromephrosis. A year later she was referred to me in the eighth month of pregnancy, and I found that the tumor had quadrupled in size, so that the conjugate was contracted to two inches and a half. I performed Cesarean section two weeks before term (the child is now eight years old), and the patient remained in good health for four years, when she again came under my care with a large pyemophrosis, from which she succumbed two weeks after admission to the hospital, her condition being so bad that an operation was deemed unjustifiable. The specimen, which is now in the pathological collection at the University and Bellevue Hospital Medical College, is of unusual interest, and furnishes a striking illustration of the fact that the position of a fibroid complicating pregnancy is more important from an obstetric standpoint than its size.

Another case illustrates even more clearly the influence of pregnancy on the growth of fibroids.

The patient, aged twenty-five years, when three months pregnant, was found to have a sessile subserous fibroid of the size of an orange, in the lower uterine segment posteriorly, but quite movable. The tubes and ovaries were removed by an eminent surgeon, with the view of arresting the growth of the tumor. The operation, of course, did not accomplish this result, and the neoplasm continued to enlarge as pregnancy advanced, until at the time when I saw the patient (at the sixth month) it had doubled in size and filled the cul-de-sac, although it was not impacted. My advice to wait until near term and then to do a Porro operation was rejected, and labor was induced, the fetus being removed piecemeal with great difficulty and no little risk to the mother, who still has her tumor, but is without ovaries or any hope of future maternity.

In connection with this case I may be permitted to refer briefly to another in which the danger of pregnancy complicated with fibroids is even more forcibly demonstrated. The patient was the wife of a doctor, and was herself a physician. She had been under electrical treatment on account of a large interstitial fibroid of the fundus uteri, with a smaller growth in the lower segment anteriorly. She suspended treatment, became pregnant, and aborted at three months. The fetus was said to have been expelled, but the placenta was retained, and when I saw the patient she was profoundly septic. It was found to be absolutely impossible to dilate the long, rigid cervix canal on account of the presence of the lower tumor, and not even a sound could be passed into the uterus. The patient’s condition was such as to lead me to believe that she would not survive a hysterectomy, although I might have performed it had she been in a hospital, and she died the next day. In this case it was clear that the tumors had rapidly increased in size under the influence of pregnancy. It seemed incomprehensible that a woman with a medical training should have been willing to marry, knowing that she had a large fibroid, and that her husband and herself did not recognize the danger of allowing pregnancy to continue under the circumstances.

As regards the influence of the neoplasms on the course of pregnancy, it may be said in general that it may proceed normally, even in connection with interstitial and impacted subserous growths. With intrauterine neoplasms complicating pregnancy I have had little personal experience, though I believe that when small they are less apt to disturb the course of pregnancy than to become a source of danger by reason of their tendency to undergo degenerative changes after delivery.

That pregnancy may be entirely masked by fibroid tumors is shown in the two following cases:

An unmarried woman, aged thirty-three years, had noticed a large mass in the lower abdomen a year before she came under my observation. It gave rise to no symptoms until three months before, when it began to grow rapidly and caused marked pressure effects. In the mean time menstruation had been absent. The possibility of pregnancy was strenuously denied. There were no breast changes or other symptoms. Suprapubic growth being removed. The uterus contained a three months’ fetus, which it was difficult to believe could have developed much longer on account of the encroachment of the tumor upon the uterine cavity. She made a rapid recovery and was discharged on the twenty-first day.

An unmarried colored woman, aged forty-four years,
was sent to me with multiple fibroids filling the entire abdomen and extending as high as the stomach and liver. She was supposed to have reached the climacteric. Little could be learned with regard to her history, except that the neoplasm had grown rapidly during the last four months, giving rise to pain, dyspnea, and edema.

Abdominal hysterectomy was performed and a four months' fetus was found within a long, narrow uterine cavity, situated in the midst of the mass of fibroids. She made an afebrile recovery. I did not think it worth while to inquire too curiously into the causes of the interesting combination of physiological and pathological conditions in these two cases, feeling that they were doubtless obscure to the patients themselves.

The tendency of gravid fibroid uteri to expel their contents prematurely has often been emphasized, but I believe that too much stress has been laid upon it, as well as upon the subsequent danger of hemorrhage. That there is some risk of torsion in the case of pedunculated growths is well recognized; in fact, I have just discharged from the hospital a patient in whom this accident occurred six weeks ago, before the fifth month of pregnancy. I operated without delay, removing a small tumor, which already showed evidences of beginning necrosis. Convalescence was normal, and I have every reason to believe that she will go on to full term and have a natural delivery, as in a previous case.

It is often asked, Should we advise young women with fibroid tumors of the uterus not to marry? Under some conditions, yes, if we detect the growth before marriage. But in the majority of the cases they give rise to no symptoms and are only discovered by the accoucheur who follows the commendable practice of examining his patients during pregnancy. It may be said that any fibroid in a young woman which gives rise to marked symptoms (hemorrhage, pain, and pressure effects) should be regarded as a positive contraindication to marriage. But love often laughs at gynaecologists as well as at locksmiths. Fortunately, many patients with fibroids remain sterile, though others may become pregnant under apparently impossible conditions.

A young woman entered the Woman's Hospital, while I was house surgeon, on account of a large interstitial fibroid, which gave rise to exhausting hemorrhages. She refused operation (fortunately for her, as hysterectomy was almost invariably fatal in those days), and after remaining for several months was discharged with strict injunctions to avoid matrimony. She promptly married, became pregnant, aborted at three or four months, and nearly lost her life from hemorrhage.

Certainly marriage for a woman with an intrapelvic tumor is rather an interesting and uncertain experiment.

My views with regard to the treatment of fibroids during pregnancy have been outlined in the cases reported. I am fully in accord with the conservative trend of modern abdominal surgery, and would not interrupt the pregnancy if it were possible to prolong it, without undue risk to the mother, until the fetus was viable. An elective Porro operation at the present day is attended with no more danger than a supravaginal amputation at the third or fourth month. Before deciding positively about any operative interference an examination under anesthesia is advisable, when the condition may prove to be such that the case may be safely left to Nature.

27 East Sixty-fourth Street.

PEMPHIGUS CHRONICUS VULGARIS OF THE LARYNX AND MOUTH.*

BY J. H. BRYAN, M. D.,
WASHINGTON, D. C.

The following brief sketch of a case of pemphigus chronicus vulgaris affecting only the mucous membrane of the larynx and mouth is of interest on account of the rarity of this affection.

In this country, at least, it must be extremely uncommon, for I am familiar with only one or two reports of cases by American authors, the most noticeable one being by Dr. Lewis H. Miller, of Brooklyn, who, in the New York Medical Journal for July 3, 1897, reports one case.

The foreign literature is, however, much more replete, especially that of the Germans. The younger Schröter, however, does not consider it such an uncommon affection, having had a personal experience of five cases.

Mrs. —— consulted me in October, 1898, for the first time, complaining of certain indefinite sensations in the region of the larynx, and stated that for six months or more she had had trouble with the throat. The attacks were frequent, but not of long duration, the principal sensation being that of a foreign substance in the larynx.

She has always enjoyed good health, save for occasional attacks of muscular rheumatism, which have not been severe enough to occasion her much inconvenience. Her appearance gave me the impression of a well-nourished person, although a little paler than usual.

The examination showed the nose, nasopharynx, and pharynx in good condition; but with the mirror a small white membranous deposit, about a quarter of an inch in diameter, was observed on the laryngeal surface of the right half of the epiglottis.

While in the act of making a local application with a cotton-tipped applicator, this deposit was detached and brought away on the cotton. The membrane beneath was red, but it did not show any loss of substance such as is met with in the various forms of ulceration that affect mucous surfaces. I sent this piece of membrane, which was of considerable thickness, to Dr. Jonathan Wright, requesting him to make an examination

* Read before the American Laryngological Association at its twenty-first annual congress.
of it for me, at the same time venturing the opinion that we had in all probability a case of simple membranous laryngitis to deal with. I tried also to reassure the patient her affliction would soon be a thing of the past. In less than four days she returned to the office saying the trouble had returned, and she felt it on the left side of the throat, referring to the larynx. On examination a deposit of membrane of the same character, and about the same size, was observed on the left half of the laryngeal surface of the epiglottis—the seat of the former deposit looked perfectly normal.

About this time I received a statement from Dr. Wright, giving it as his opinion the case was one of chronic pemphigus vulgaris, and also giving me the results of his microscope and bacteriological examinations, which were as follows: Under the microscope the membrane showed a fibrinous deposit containing numerous round cells, but no epithelium; staining with Gram's method showed a large number of cocci, but no bacilli.

I am free to confess that up to this time I was not familiar with this condition, never having seen a case before. There have been frequent outbreaks since the original observation, the membranous deposit making its appearance on one half of the epiglottis, disappearing in a few days to reappear on the other half of this cartilage.

The patient denies ever having had any cutaneous disease. About three weeks ago she complained of feeling much worse, especially of being very nervous and weak. The examination revealed a small deposit on the epiglottis, and for the first time the gums were noticed to be quite red and swollen. There was a membranous deposit on the upper left half of the gum about an inch in length, and a smaller deposit on the lower gum just below the incisor teeth. She was a little more anemic looking, and she complained of a slight swelling of the lower extremities.

An examination of the heart showed nothing abnormal, except that the sounds were not quite as clear as they should be in a vigorous person.

A urinary analysis showed a slight trace of albumin with a few blood-corpuscles and pus cells, and a few granular hyaline casts.

An examination of the blood showed nothing abnormal.

Pemphigus is a varied form of skin affection characterized by the formation of bullae, and whether it be of the benign or malignant variety dermatologists consider it a very rare disease. The eruption on the mucous membrane of the upper air-passages is noticed in all forms of the disease, being more common in the chronic than in the acute variety. It is generally secondary to the skin eruption, gradually extending into the mouth, pharynx, larynx, and into the trachea and bronchi; and also occasionally affecting the conjunctiva. There are, however, a number of instances in which the eruption makes its appearance on the mucous surfaces primarily, as in my case; and cases are cited by Mershand, Bleibtrecu, Penrose, Carré, and Miller. Generally the appearance of the eruption on the mucous membrane is characterized by the formation of a bleb, which is filled with a yellowish fluid such as we find in the bullous formations on the skin. This bleb finally ruptures and a milky white membranous deposit remains.

It is questionable whether the appearance of the eruption on the membrane is always accompanied by the formation of bullae. In my case I have never been able to recognize them, although the patient is able to determine the time of the appearance of the eruption on the membrane by a pricking sensation in the larynx, and she has been in my office within half an hour of this time.

According to Chiari, the bullae are the result of a rapid exudation, while in a slow exudation it simply causes a raising and discoloration of the epithelium, giving the grayish deposit the appearance of a diphtheritic membrane. Acute pemphigus of the mucous membrane is always accompanied by a high fever, while the chronic variety is generally without fever, and occurs in those who feel otherwise well.

The diagnosis of pemphigus of the larynx, when it is secondary to the skin eruption, offers little or no difficulty, but it is quite another matter when it makes its appearance primarily on the mucous membrane. It is to be distinguished from diphtheria, tuberculosis, syphilis, herpes of the larynx, and finally the caustic effects of acids or lye.

The etiology of pemphigus is extremely obscure, the majority of authors holding to the tropho-neurotic theory. Microscopic and bacteriological examinations have been made in Mandelstamm's, in Miller's, and in my case, all of which were of a negative character.

This is essentially a chronic disease, and may last months before disappearing or wearing the patient out.

Local applications have no influence whatsoever, alkaline washes probably giving the patient some relief from the constant irritation in the mouth and larynx.

The only remedy which is supposed to have the slightest influence on the disease is arsenic, either in the form of the Asiatic pill or Fowler's solution carried to the point of tolerance. This latter remedy has acted well in my case. The patient at the time of writing has not had an outbreak either in the larynx or mouth for two months.

**Dry Heat of High Degree as a Therapeutic Agent.**

By C. E. Skinner, M.D., New Haven, Conn.

(Continued from page 626.)

Case III. Chronic Rheumatism.—I was called to see Mr. H. A., mechanic, June 6, 1898. He was suffering from acute inflammatory rheumatism involving left knee and ankle, both badly, but the knee the worse. At that time I was not acquainted with hot air, but gave him the best treatment then at my command—viz., a good, vigorous salicyl saturation. To make a long story short, as my business with this case, as referred to in this article, does not apply to this early stage of it, the patient got lamely up from his illness after some weeks, but the disease settled in the foot at the medio-tarsal
articulation and became chronic in spite of all I could do. Salophen, alkalithia, etc., I administered in succession. Local means were of no avail, and he had stopped treatment in despair, so far as I was concerned, substituting in my place his friends and the drugists, who were endeavoring to help him through the medium of household recipes and patent medicines—an experience no more new than happy for any of us, I fancy. By November, 1898, I had become sufficiently familiar with hot air to believe it would be worth trying in this case, and I hunted him up. He was still suffering, as he had been for three months, not having been able to remain at his work all day a dozen times since June, and many days having to remain at home altogether. He was glad to try anything which promised him relief, and I gave him his first treatment on November 13th. Pain entirely disappeared during treatment, but the sensation of stiffness remained as bad as ever. Patient was delighted at the freedom from pain. He was directed to return on the second day.

November 15th.—After walking home on the day of first treatment pain was as bad as ever, and has been ever since. Administered hot air and requested him to return on the second day.

17th.—Reports himself as feeling much better. Pain returned on the day following last treatment, and has remained ever since, but not nearly as severe as before. Hot air administered.

19th.—Had a little pain following his walk home after last treatment, but yesterday and to-day has been entirely free from it. Hot air administered, and patient directed to report in five days anyway, and sooner if pain appeared.

24th.—Patient reports no pain at all and no stiffness since last treatment. Foot feels as good as it ever did. Treatment was administered once more at this time but the trouble had ended six days previously. The cause of five months of suffering and disability had been eradicated in four days.

Case IV. Chronic Sciatica.—M. T. M., seventy years old. Had suffered with sciatic rheumatism constantly for the past two years, and almost constantly for the past four years. Had tried various methods of treatment under both professional and lay guidance, with no satisfactory results. First consulted me September 24, 1898. I treated him by the usual methods with fluctuating results until November, by which time I decided to try him on hot air.

November 8th.—My operating room is on the second floor, and I observed that in ascending the stairs patient was obliged to place both feet on one stair before he could effect the next rise, because of inability to bend his hip joint. Treatment was administered and pain had disappeared in ten minutes. After treatment, for the first time in many months, he was able to place the foot belonging to the infirm leg upon the opposite knee to lace his shoe. Walked downstairs without pain or stiffness.

9th.—Felt slight painful twinges this morning, but nothing else since treatment except on going upstairs. Hot air administered and patient requested to return the next day but one if he continued to improve, but sooner if he grew any worse.

11th.—No pain at all since the evening of November 9th, and he says that people whom he meets are remarking that he "doesn't walk lame any more." Extreme flexion of thigh upon body causes pain, but I am unable to provoke it by any other manipulation. Treatment administered and patient told to return in a week anyway, and sooner if symptoms returned.

17th.—Patient reports no pain or stiffness at all since last treatment. Leg movable in any direction and to any normal extent. No pain elicited by any sort of manipulation. Has been accidentally wet through twice since his last visit and been unable to change his clothing for some hours afterward, with no unpleasant sequela. Hot air was once more administered and patient discharged with instructions to call again immediately if any more trouble appeared, which he promised to do. He has not appeared since. Four years of suffering terminated in as many days.

In spite of these results, which are pregnant with significance and have been constantly paralleled in subsequent cases under my care, opponents of the measure are not wanting. Let us consider the principal grounds alleged as supporting this opposition.

Hot air has been frowned upon because "its sedative action lasts but a short time, results in no permanent benefit to the patient, and does not shorten the duration of the disease," and because "if we must give medicine anyway, we might as well give it without the troublesome and expensive hot air."

To the first I would answer that it is our imperative duty to relieve the patient from all the pain possible. If we can relieve him for only a short time, then he should be given the benefit of our ability to that extent even if it ended there. When it is possible, however, by successive repetitions of a measure to cause one period of relief, however short, to follow immediately after a preceding period, we are securing a result which amounts practically to permanent relief; and when the repetitions of the measure are not inimical to the patient's welfare, and they certainly are not when the agent employed is hot air, it is unjustifiable to withhold this comfort from the sufferer. In addition to the humanity of it we secure a directly favorable influence upon the course of the disease by protecting the victim's nervous system from the depressing influence of pain and loss of sleep, both of which are powerful disturbers of tissue metabolism. Hence hot air is of "permanent benefit to the patient" when properly and intelligently applied with sufficient frequency—every three hours if necessary.

In reference to a so-called permanent "cure" of the disease, no one who stops to think a minute will ever expect to keep a patient free from rheumatism all the rest of his life by any one course of any means of treatment. All that can be done is to rid him of the present attack by clearing away the micro-organisms and their products that are in his system at that time, rendering him as comfortable as possible during the period of elimination. If the patient has the diathesis, and favorable constitutional and environmental conditions obtain, nothing can prevent a fresh invasion of germs and the development of another attack. When a patient recovers from typhoid fever or pneumonia we do
not promise that he will never suffer from it again. We can only be sure that he has recovered from this one attack. Favorable conditions will certainly induce another, but we do not for that reason clamor for a permanent cure of typhoid or pneumonia.

If not in these diseases, why then in rheumatism, which differs from them in this connection only in so far as that its specific morbid elements are much more plentifully distributed, whereby more individuals are exposed to its influence, and that when once they have gained a foothold in the system they possess the power of reproducing themselves, without any further reenforcements from the outside, to an extent which renders its duration, when left to itself or inefficiently treated, absolutely indefinite? Rheumatism is not, like the others, a self-limited disease. Is it not much more logical, then, to welcome any measure which enables us to end an attack of rheumatism more quickly and comfortably than was possible before rather than to vilify it because it does not produce an instantaneous cure and render the patient immune for life? Even if the disease returned every three months, is not the possession of a measure which enables us to end the attack of such a disease as quickly and comfortably as is the case with hot air, something upon which we should most sincerely congratulate ourselves rather than seek to discredit the remedy?

As for the influence upon the "duration of the disease," as I have said previously, it seems to exhibit little if any inherent curative power here when relied upon alone, but if a judicious administration of drugs had accompanied the hot-air applications, the author of this assertion would have observed a vast deal of shortening in the "duration" of his cases. It needs the help of drugs to effect a cure. Even, however, if it had no power under any circumstances of shortening the duration of the disease, the fact that it is capable of completely and almost immediately relieving the pain of such a horribly painful affection as rheumatism, without the production of any deleterious or unpleasant secondary effects, would entitle it to a place in the highest rank of therapeutic measures.

In reference to the second objection, "If we must give medicine anyway, we might as well give it without the troublesome and expensive hot air," every physician sees cases frequently in which remedies will not "take hold." One after another will be tried in increasing doses. Meanwhile the patient drags on, day after day and week after week, without any or only a slight and irregular improvement; stomach impaired, nervous system and general condition growing worse and worse under the continuous combined depressions of pain and rheumatic toxines, until he and the physician too are tempted to despair of ever being able to get rid of this "old man of the sea."

Treating these cases, which frequently will become chronic in spite of all we can do, is extremely trying and unsatisfactory to both physician and patient; and certainly any agent which will change all this and cause our medicines to act, and act rapidly, should be hailed with joy. Hot air is such an agent. When a patient is responding well to medication it may be proper enough, if he has plenty of time to stay in bed, to give medicines "without the troublesome and expensive hot air"; but when we consider that the last-mentioned agent markedly increases the rapidity with which the disease is eliminated by increasing directly and indirectly the activity of the elements with which we are combating the pathological process, it assumes an importance equal to the medicines and more than trebles their value. Even under the most vigorous administration of the salicyl and salophen regimen—and this combination is undeniably as specific in combating rheumatism as any drug we now know is in combating any disease—it takes several hours, from ten to twenty-four usually, to secure a marked remission of pain. Hot air accomplishes this in from fifteen to thirty minutes, a result which the patient at least regards as of considerable importance.

The application of this agent is more or less "troublesome," I admit, but this element of objection scarcely deserves a mention, and certainly not a discussion. When the relief of human agony is the point to be gained, a little trouble, or even a great deal of trouble, has no right to enter the problem at all.

The idea that the treatment is excessively "expensive" is founded upon a narrow and short-sighted view of the facts. Let us consider a moment. An attack of rheumatism detains the patient from his business from three days to three weeks, and occasionally three months. Infrequently an attack will prevent resumption of daily duties, at least in anything like a satisfactory manner, for six months, as illustrated in Case II, and even longer. This involves a loss of income for the patient, an outlay for his physician's fees which will be great in proportion to the severity of the case, and prolonged if the case drags, and an outlay for medicines in the same proportions. I shall only mention in this connection the outlay for a trained nurse, because the majority of those who suffer from this disease, even more than other diseases, are unable to afford a trained nurse and have to depend upon the ministrations of members of the family circle.

Under ordinary good methods of treatment alone the duration of rheumatism may be said to be measured by days and weeks. When hot air is combined with them it dwindles to hours and days. Because of this marked shortening of the period of disability the patient will lose less of his income; because of this and the rapid and marked mitigation in the severity of the symptoms he will have fewer visits from his physician to pay for; his drug-store expenditures will be curtailed, because he will not have to take drugs for such a long time or in such variety, and, if he has employed a nurse,
the saving on her wages from the same causes will be an item not to be despised. As contrasted with this, the first cost of hot air is double and sometimes quadruple that of the ordinary treatment, but it is required for such a short time that at the end of the attack the patient's finances are found to be much less impaired than when it is attempted to cure him without it. It renders a severe case comparatively mild, and a mild case very much milder. Whether the freedom from pain during the attack, and the shortening of the period during which it has to be borne, are worthy of any consideration in this connection may safely be left to the verdict of the patient.

Ever since the analogy between rheumatism and malaria was pointed out by Dr. T. J. Maclagan, of London, in the early seventies of this century, thereby suggesting and subsequently demonstrating a microbic instead of a lactic-acid causation, there has been a tendency in the minds of many, and I think I may safely say most, of us to deride and discredit his suggestion that the salicyl compounds stood in as much the relation of a specific to rheumatism as quinine does to malaria. Nobody has denied that the salicyl treatment was the most efficacious at our command in this disease, but its claims to specificness have been assailed. The only tenable ground upon which its assailants have stood is that it failed to cure in many cases. Let us see if this apparent weakness possesses the power of invalidating these claims, and if hot air will not furnish another link in Dr. Maclagan's chain of analogy.

First, if any remedy is to be of benefit in any disease, it must be administered properly—i.e., in adequate dosage and in such form or combination that it can be as easily assimilated and with as few disadvantageous effects upon the patient as possible; and second, and just as necessary, the patient's organism must be susceptible of adequately assimilating the remedy. No matter how specific a medicine, if the victim's stomach is not capable of properly passing it on to the circulation, or if the mysterious sympathetic nerve centres controlling the metabolic activities which represent assimilation are in abeyance from ptoamine intoxication or other causes, give it in as large doses as we please, and no result will follow. Malarial victims are not infrequently encountered who are taking quinine to the point of intoxication, and shaking every day in spite of it. I have seen a patient with a rheumatic focus in her ankle swallow salicin at the rate of twenty-six grammes a day, and the infection spread successively to finger joints and elbow notwithstanding. Under these circumstances patients are unquestionably getting a sufficient dose of the remedies, and, if the preparations administered are moderately soluble under the conditions obtaining in their stomachs, and not sufficiently irritating to goad that long-suffering organ into exhibiting intolerance of their presence, the blood current will be saturated thereby. We get no effect or little effect upon the disease, however. The drug is not being assimilated. Can we explain this arrest of the assimilative function; can we correct it, thus enabling the suffering tissues to appropriate the specific remedy, thereby securing the destruction of their assailants the microorganisms, and, if so, how?

A living organism is made up of parts, each consisting of smaller parts, and each of these in turn formed by the union of still smaller collections of other yet more diminutive components, and so on until we finally arrive at the primordial protoplasmic cell, which so far as we now know, is the ultimate unit of living tissue. There is reason to believe, however, that this cell is but a collection of other bodies the structure of which is so subtle as to have eluded so far all our means of discovering them. That it possesses life and vitality is proved by its power of reproducing itself spontaneously and of reacting to stimulation; but where these inherent powers lie, of what they consist, or by what process, chemical or otherwise, they manifest themselves, we know nothing. It is, however, through the exercise of just these properties, which at present are buried from us in mystery, that the assimilative function is accomplished.

The smallest and simplest organ of the body consists of a collection of these primordial cells, and its proper nutrition and the maintenance of its integrity, consequently its function, depend upon the proper nutrition, maintenance of integrity and function of each and every of the primordial cells which unite to form it. The part of the body next higher in organization consists of a union of two or more of these collections of primordial cells, all interdependent upon each other, and the complex whole dependent for welfare and nutrition upon the welfare and nutrition of the ultimate primordial cells, until in the complete human body we have a vast number of these cell combinations, all interdependent upon each other for proper functioning, and the whole organism dependent ultimately upon the health of the primordial cell.

The health of these small but important individuals may be impaired in two ways: first, directly, by contact with some substance which will disintegrate their structure, as arsenic, for instance; second, indirectly, by impairment or destruction of some distant organ or group of contiguous cell combinations through that mystical medium by which every part of the body, however minute, is in close communication with every other part, which we call nervous impulse. Witness the arrest of metabolism caused by shock, also the influence of general debility upon local tissue repair.

All poisons do not kill a human body in the same way. Some, as arsenic, kill by directly disintegrating the primordial cell structure; others, as strychnine, kill by acting upon groups of cell combinations, affecting the primordial cells composing them only secondarily. Victims of arsenical poisoning, therefore, show its ravages upon every tissue in their bodies, while death from
strychnine occurs in the vast majority of cases from asphyxias caused by unyielding spasm of the respiratory muscles during a convulsion. The small proportion of deaths occurring while the patient is quiet between convulsions are probably due to exhaustion of primordial-cell vitality dependent upon the induced excessive activity of nerve tissue as a whole, as much as to a direct action of the poison upon protoplasm, which last is of the nature of a paralysis rather than an integral destruction. This latter is the point which concerns us here, and is proved by the experiments of Vulpian, who showed that even when nerve tissue was poisoned by large enough doses of the drug to produce paralysis, without antecedent convulsions, the nerve would regain its function when the effect of the poison wore off. The time required for this was too short for regeneration to have taken place, and demonstrates that the paralysis was not due to destruction of the ultimate radicles forming the nerve, but to inhibition of function through action upon it as a whole.

We thus see that inanimate toxic agents exercise selective affinities as regards the tissues, primordial cells or groups of them, unorganized or specially organized tissues, upon which they can act. These differing affinities are, of course, largely dependent upon structural differences existing in the poisons themselves, but they further demand for their full explanation the admission of the fact that divers tissues also exhibit marked differences in structure, by reason of which some of them are unresponsive to agents or processes which do not directly destroy the primordial cell. Of the nature of these differences we are as yet entirely in the dark.

The fact that they exist, however, would lead us to expect that the micro-organisms in diseases owning microbic etiology would find a soil favorable to their growth in some organs or tissues having more or less specialized function and not in others; that the ptomaines emanating therefrom would exhibit the same properties in this connection that we encounter in other poisons, and that these tissues would always be found more or less affected in the same way in all cases of the same disease, and observation proves this to be true.

The malarial parasite always attacks primarily the red blood-corpuscle, and whatever phenomena obtain in the body as a whole are induced secondarily through the parasite’s influence upon the health of the blood-corpuscle, and also by the direct effect of ptomaines produced from itself and circulating in the blood, which pick out and expend their virulence upon the tissues most susceptible to their action. The red blood-corpuscle is technically a tissue; hence we always have the same tissue affected in the same way in all cases of malaria.

The paroxysm, to be sure, does not always occur in the same intensity, or with the same proportionate intensity of its elemental phenomena, but this is explicable by the assumption that it is caused by increase in the saturation of the blood by ptomaines thrown off during the periodical reproduction of the parasite, which, bathing freely every part of the body, would pick out the tissues most susceptible to their influence and act upon these in proportion to the amount of poison present: the more ptomaines, the harder the paroxysm, and vice versa. When quinine is given in insufficient doses the activity of the parasite is impaired, and, though we still get a paroxysm, it is of lessened intensity, because the impairment of the germ’s activity results in a lessened ptomaine production, wherefore the susceptible tissues are less profoundly influenced.

The same gross result obtains when the quantity of the specific administered is adequate but impairment of assimilation exists. In the first instance sufficient quinine is not available for appropriation through metabolic absorption by the red blood-corpuscle; in the second, enough of the beneficial agent is present, but impaired metabolic capacity prevents adequate absorption. This impairment is due to debility of the general organism, which is shared by each and every one of its parts, because they are all intimately connected with each other by the sympathetic nerve distribution, are all interdependent for welfare and preservation of functional integrity, and an accident to one has an immediate effect upon the function of all the others. In a debilitated man every one of his primordial cells is debilitated.

Hence, in malaria, provided no preexisting debility is present, adequate dosage with quinine, as soon as the disease is established, will almost invariably effect a cure. In the cases in which an insufficient quantity of the specific has been administered in the first place, thereby allowing the micro-organisms and their products to act upon the organism as a whole for an extended time, though with diminished virulence, the metabolic function becomes impaired and we may give quinine by the pound and the patient will not recover. When debility exists at the time of invasion this impairment is of course sooner and more profoundly induced. That, however, does not vitiate the drug’s claims to being a specific poison to the parasite. The fact is not that the axe can not cut the wood, but that the wood has been cased in steel. If we remove the steel the axe will cut as well as ever. By what means do we accomplish this object?

(To be continued.)

A PLEA FOR THE FURTHER USE OF CARBOLIC ACID.

By FREDERIC J. ADAMS, M. D.

One of the best of our bactericides is carbolic acid, which has probably been used as extensively as any of our antiseptics. The only drawback to its employment has been that when used in strong solutions it has de-
stroked the tissue. Now that we have a complete antidote for the acid we have nothing to fear from a very free use of it in its pure form. My method has been for the past eight months to use the crystals, liquefying them, and applying the fluid to the surface with a camel’s-hair brush. As soon as the surface appears white I apply alcohol (chemically pure) in copious quantities, and the work is over.

I have been using this treatment in all cases of cellulitis, felon, about ulcers with widespread exudate, carbuncles, erysipelas, and, in short, any and all inflammatory conditions where streptococci and staphylococci are present. My latest experiment was with a case of gonorrhceal vaginitis, where the vagina in its entire depth was exceedingly swollen and the labia were nearly impappable. I saturated a tampon with pure carbolic acid, inserted it into the vagina, let it remain thirty seconds, withdrew it, and drenched the parts with one quart of alcohol. The labia had been treated similarly previously. The following day the discharge was meagre and the swelling and inflamed area had subsided. A second treatment effected a complete cure. In no case have I had to make a third application of the acid.

Knowing that alcohol removed all dangers of tissue destruction from the action of the acid, I reasoned thus: We have been using carbolic acid for a long time in the form of from 1-to-20 to 1-to-60 solutions as a compress for inflamed conditions with uniformly good results. Why should we not obtain better and quicker results with pure carbolic acid, which will penetrate and destroy streptococci and staphylococci?

Here is a partial list of patients treated by me and, under my direction, by Dr. Hair at the Emergency Hospital Dispensary, of Bridgeport:

Case I.—John McD., aged twenty-one years. Infected wound on right hand at the thumb, caused by copper wire. Lymphatics very red to the elbow, glands in axilla swollen so that the patient could not bring his arm to his side. Carbolic acid, fifty-per-cent. solution, applied to thumb, back of hand, and along the lymphatic channels. Alcohol applied at the expiration of sixty seconds. Greatly relieved. Patient ordered to report the following day. Much improved. Third day, cured. The fifty-per-cent. solution was used by mistake.

Case II.—Mary S., aged fifty years. Cellulitis of right hand and forearm, lymphatic channels red and swollen, axillary glands greatly enlarged. Pure carbolic acid painted over entire hand, forearm, and lymphatic channels. Bathed thoroughly with alcohol. Reported next day cured.

Case III.—Mary M., aged seventeen years. Employed in a cartridge factory. Erysipelas of the left hand. Applied pure carbolic acid at my office; bathed in alcohol. Reported following day much improved, pain gone, swelling reduced one half. The same treatment was followed the next day. The third day the patient reported at my office cured, no pain or swelling, and with perfect use of the hand.

Case IV.—Millie M., aged six years. Felon on right thumb. Treated with pure carbolic acid and alcohol. Upon the following day cured.

Case V.—Charles H., aged twenty years. Inguinal adenitis due to chancroid. Two applications of carbolic acid with alcohol baths to the afflicted parts were followed by complete recovery.

I think these few cases, taken at random, will show the efficiency of the treatment.

I merely wish to add the history of an attempt at suicide with carbolic acid treated by Dr. Hair with alcohol.

Patient, Mary S., prostitute, aged thirty-six years. Found by ambulance at 10.25 A.M. One pint of alcohol poured down throat at once. 10.25 A.M., one pint of milk. Hypodermic, thirty minims of whisky. 11 A.M., four ounces of alcohol. 11.20 A.M., four ounces of whisky. 11.35 A.M., four ounces of whisky. 12 M., four ounces of whisky. 12.15 P.M., two ounces of whisky. 12.45 P.M., two ounces of whisky. 1.45 P.M., two ounces of whisky. The patient was then removed to the General Hospital, where she showed no signs of alcoholism and very little shock. In two weeks she was discharged from the hospital and returned to her former vocation.

Dr. Hair was relieved at 12 M., hence the decrease in the dose. The reason whisky was substituted was on account of the small quantity of alcohol (chemically pure) in the hospital.

I make no claim of being the first to discover the effect of alcohol as an antidote to carbolic acid, but merely urge the fraternity to a further use of the pure acid, and can assure them of splendid results with cases that have formerly been tedious and trying, and only recovered to bear great scars where the patient had been lanced.

DERMATITIS FOLLOWING THE USE OF ORTHOFORM.

By G. E. DECKER, M.D., DAVENPORT, IOWA.

During the last year and a half the writer has used orthoform as a dressing in minor injuries with results that justified all the statements made for it as an analgetic and antiseptic powder, except in two cases, which should be reported. The conditions in both these cases were identical, and, as no antiseptic but mercuric chloride was used, it seems clear that the orthoform was to blame:

Case I.—A machinist, aged twenty-three years, healthy, came to the office suffering from severe confusion and laceration of the right little finger. There was considerable loss of tissue, including the finger nail. The finger was carefully cleansed with 1-to-1,000 bichloride solution and dressed with orthoform powder and bichloride gauze and bandage. Patient returned in a week and the wound was found to be clean and in good condition. Dressed with orthoform as before.

Three days later he again returned, complaining of...
much discomfort, and on examination the following condition was found: Finger swollen, painful, and with entire epidermis undermined by small confluent blisters which contained a very sticky serous fluid. There was also a peculiar odor like that of freshly baked bread, which odor continued as long as there was any of this serous discharge.

The loose epidermis was removed and the finger cleaned with three-per-cent. carbolic-acid solution, and iodiform gauze used as dressing. Orthoform discontinued.

In a few days the blisters had spread to the rest of the hand and part of the body, especially the scrotum and legs. There was considerable itching. A free serous discharge from the fingers necessitated changing the dressings two or three times a day. After two weeks the fingers and hand became dry and the blisters disappeared from the body, the original wound healing at the same time.

Case II.—A machinist, aged twenty years, healthy. Injury consisted of a severe laceration of index finger of left hand. First attention was similar in all respects to that of Case I. This case occurred in the practice of a colleague and was seen during his absence about two weeks after the injury. The epidermis was then found to be entirely loosened and was removed in one piece by splitting it down the dorsum of the finger. There was the same sticky serous discharge and the same peculiar odor. Small blisters were appearing on the other fingers and palm of hand.

The wound and fingers were swabbed with camphophenique and dusted with acetanilide powder. This dressing was repeated daily and in about a week the discharge ceased, the other blisters dried up, and the wound healed by granulation.

**Therapeutical Notes.**

*Hydrastis Canadensis* in Haemoptysis.—According to Dr. Sabadini (Gazette hebdomadaire de médecine et de Chirurgie, October 15th), Scarpa prescribes the following:

1. Fluid extract of hyd- 

2. R drastis canadensis. 7 grains; 

3. Tincture of hyd- 

4. drastis canadensis; 

5. M. From twenty to fifty drops to be taken three times daily. When the haemoptysis is arrested the treatment should be continued for two or three days, and the dose then rapidly reduced to cessation.

Should obstinate cough prevent the hemostatic effect, morphine or codeine should be added, in the following proportions: To the foregoing prescription add from 4 to 7 grains of codeine, or from 3 to 4 grains of morphine. The same dose should be given as before. Scarpa insists on the necessity of the preparation being fresh.

**Strontium Lactate in the Treatment of Renal Disease.**—Dr. S. Browne (Wiener medizinische Presse, 1899, No. 5; Centrallblatt für innere Medicine, November 4th) finds by experiments on animals that strontium lactate causes a general lowering of the blood pressure. If more than a grain for each kilogramme of the animal’s weight is given, renal irritation is induced. The diuretic action depends, not on a direct influence of the drug on the renal epithelia, but in all probability on dilatation of the blood-vessels of the kidney, which in turn is dependent on the renal nerves. Clinically, diuresis occurs in the majority of cases, with diminution of the amount of albumin in the urine, so that the drug works favorably in many cases of Bright’s disease that are not too far advanced.

**The Treatment of Tuberculosis.—Riforma medica for September 5th gives this prescription:**

1. Powdered e cinematic acid ... 75 grains; 

2. Oil of sweet almonds ... 150 ° 

3. Yolk of egg ... No. 1; 

4. Chloride of sodium in three- 

5. quarter-per-cent. solution 

6. sufficient to make an emul- 

7. sion of ... 1,500 grains.

To be used by intravenous injection into the fold of the elbow, or where the saphenous vein passes beneath the internal malleolus. Fifteen grains of the solution to be used daily.

**Gallnut for Hemorrhoids.**—The Medical Times for November cites Dr. Roger S. Chew, of Calcutta (Medical Age, August 25th) as saying that he never performs an operation for hemorrhoids now, as there is a very simple remedy—so simple, indeed, that the profession refused to accept it because it was unscientific. He also laughed at it at one time, but results brought the laugh against him. His tutor was an unlettered, untitled fakir, who dropped into his surgery one morning as he was asking a man with a huge bunch of extremely painful and bleeding hemorrhoids whether he would submit to operation. “Sir,” said the fakir, “pardon my interference. Will cutting away swollen veins alter the current of the blood permanently? That man is afraid of the knife. Let me whisper in your ear. Take a *chota barna* (the lesser gallnut); boil it as you would a coffee bean; then powder it, and mixing the powder with a little fresh butter, let the man apply it to the piles after each stool. If it fails to cure him, may Allah send me to perdition.” Don’t muddle this, says Dr. Chew, with the “unguentum gallas” of the pharmacopoeia. The author tried it. Eight applications cured the man, and to his surprise the first application stopped the bleeding entirely. Since then Dr. Chew has cured some hundreds of cases with the same thing.

**For the Sweating of Tuberculosis.—Riforma medica for September 5th attributes the following to Sieferl:**

1. Agaricine ... 7 1/2 grains; 

2. Dover’s powder ... 113 1/2 “ 

3. Powdered mallow; of each ... 60 “ 

4. Mugilae.

5. Make one hundred pills. From one to two to be taken in the evening.

**Incontinence of Urine in Elderly or Nervous Women.—The Cincinnati Lancet-Clinic for November 4th quotes the following from the Medical Press and Circular: When there is a frequent desire to pass water, or it runs away in the act of coughing, sneezing, or laughing, it is generally due to the want of power in the vesical sphincter. In such cases tincture of cantharides will be found of the greatest service if given in small doses of one minim in water three or four times daily.**
THE PROPOSED SOUTHERN NATIONAL PARK.

The Southern National Park Association has been organized in Asheville, North Carolina, at an inter-State convention of "all persons interested in forest preservation," for the purpose of promoting the establishment of a national park in the mountainous region of western North Carolina. The movement has the cooperation of the mayor, the board of aldermen, and the board of trade of Asheville. The board of trade's parks and forestry committee, of which Dr. C. P. Ambler is the secretary, and the forestry committee of the Buncombe County Medical Society, consisting of Dr. J. A. Burroughs, Dr. S. Westray Battle, Dr. J. A. Watson, and Dr. John Hey Williams, are also active in the matter. The association will endeavor to secure a congressional appropriation and the appointment of a commission to inquire into the desirability and feasibility of establishing the proposed park and game preserve.

It is pointed out that the few national parks we now possess are all in the North, and that strong arguments in favor of maintaining timber reserves in Minnesota and elsewhere will be presented at the next session of congress. Apparently the South thinks its turn ought to come now, and we must say we think it is justified in so thinking. As Southern Pictures and Pencilings puts it, "the country has given millions to the development of the great Yellowstone Park with its curious formations and freaks of Nature and its dreary grandeur, and the Eastern States have their breathing places in the mountains and by the sea which have been secured to the people either by the trend of events or by governmental intervention. These facts have been in the minds of the people of the South as well as those who have visited and considered the conditions weighing on the people of the South and of the Carolinas in particular, and for many years—nearing a quarter of a century in fact—there has been more or less talk of the magnificent opportunities and the great advantages to the country at large in the establishment of a national park in the Blue Ridge or Great Smoky Mountains or connecting ranges."

Forestry has been too long neglected in the United States, as sanitation was until a little more than thirty years ago. The two protective movements touch each other at more than one point, and we can not doubt that the dawning of general interest in the preservation of what remains of our fast dissolving forests will go far to help along the efforts of sanitarians. That being the case, we feel that we have only to mention the matter to secure for our Asheville friends considerable cooperation by the medical profession throughout the country. A form of petition to congress has been printed and circulated, and we do not doubt that it will be generally signed by physicians in all sections of the country.

THE MEDICAL SERVICE OF THE ARMY.

Surgeon-General Sternberg has favored us with a copy of his report to the secretary of war for the fiscal year ending June 30, 1899, dated October 12th. It is a voluminous document, and the limitations of our space will admit of our mentioning only a few of its features. Naturally, the most interesting part of the report, from the professional point of view, is the section devoted to the health of the army. It is based upon only a fair representation in the form of sick reports, as regards the volunteers, for some of the regimental surgeons in Cuba failed to furnish such reports for July and August, 1898. There is satisfactory evidence in this part of the report that the mortality for the year, whether from sickness or from injuries, was far smaller than was to be expected under the stress of the hasty improvisation of a volunteer force sufficient to undertake the task of wrestling Cuba from Spain. In particular, the number of deaths from yellow fever fell decidedly below what had been expected. Typhoid fever proved to be the leading cause of mortality, but in no instance was its access to a camp or garrison shown to have taken place by way of the regular water supply.

The surgeon-general remarks that at the outbreak of the recent war the purity of water supplies for troops in the field was a subject to which much consideration was given. What was desired was a sterile water, a water free from all bacterial infection. Boiling was the readiest way by which a drinking water could be sterilized; but it was found difficult without special facilities to provide boiled water for a marching command, and, moreover, many soldiers have a distaste for boiled water on account of its flatness from loss of the gases held in solution in the fresh water. By a combination of an asbestos strainer and a filtering cylinder of compact infusorial earth, the surgeon-general had hoped to be able to provide a means, at once portable and efficient, for rendering an infected water harmless. This combination was sent to some of the com-
mands for trial. They were brought into service at Camp Meade, Pennsylvania, not because the water there required this filtration, but with a view to familiarize the command with the method of using the filters. Some were used at Chickamauga Park, Georgia, and a few were seen by the inspectors in company kitchens at Montauk Point, Long Island. They answered their purpose very well when used intelligently and carefully handled. They were largely employed at those field hospitals which had to make use of surface waters, and occasional mention was made of them in reports from the temporary camps established on the occupancy of Cuba. At length a board of medical officers appointed for the purpose reviewed the various methods suggested, and tested the apparatus presented by manufacturers, and in its report described and approved of a rapid and economical method of sterilization by the Waterhouse-Forbes water sterilizer. The heat given out by the boiled water is utilized in heating the entering fresh water. The boiled and aerated water is delivered from the apparatus at a temperature only 4° F. above that of the entering water. It has been recommended that a number of these sterilizers be sent out for practical test by troops in the field. General Sternberg highly recommends the construction of regular sewers for camps, but he says that if such a system is considered objectionable on the score of expense or for any other reason, a trough arrangement for trap and disinfection purposes, with removal of the excreta by pneumatic pressure, may be resorted to, as has been done with satisfactory results at the Presidio and at Camp Meade.

Concerning the food supplies issued to the army during the war, in spite of all the sensational newspapers had to say about "embalmed beef," there were on file at the time in the surgeon-general’s office only two papers referring to beef supplies. One of these was a statement concerning the poor quality of the native Hawaiian beef issued to the troops in Honolulu. The other was a report of a voyage made by the Panama with sick and convalescents from Ponce to Fort Monroe, in which the medical officer stated incidentally that the refrigerated beef which he had received from the subsistence department had proved of great value during the trip. The surgeon-general does not think it necessary to change the present army ration in order to meet the requirements of tropical climates, for the articles not used are credited to the men, and their money value can be employed for the purchase of articles found more desirable.

As to the men’s clothing, the blue uniform of the regulars was universally condemned as too heavy for tropical campaigning, and the woolen undershirts as occasioning much irritation of the skin. So, too, canvas suits were found unpleasantly stiff and heavy until they had been washed several times, and the like complaint was made of khaki. It was the general experience that a light woolen undershirt was essential to prevent chilling of the body, also drawers of the same material, although some medical officers consider cotton to be preferable. A white duck uniform is recommended for garrison duty, and the khaki suit for field service. It was thought at first that the campaign hat was too heavy, and that the helmet used by the British troops in India was the best protection for the head in tropical countries, but longer experience, particularly after the rainy season set in, showed the American hat to have advantages not possessed by other forms of headgear. There were no complaints concerning socks or shoes, so they are assumed to have been entirely satisfactory.

The report closes with the following recommendations: "The medical corps of the army, which was scarcely adequate before the war with Spain for our army of twenty-five thousand men, is now entirely inadequate and should be increased as soon as is practicable. Physicians and surgeons from civil life, however well qualified professionally, as a rule are not prepared to assume the responsibilities of medical officers charged with administrative duties and the sanitary supervision of camps. The proper performance of such duties can not be expected from a physician without military training or experience, no matter how distinguished a position he may have held in civil life. Many of the commissioned medical officers of the volunteer army and of the acting assistant surgeons have made rapid progress in acquiring a knowledge of their military duties and have demonstrated their fitness for the military service. In filling vacancies in the medical corps these gentlemen should, in my opinion, have the preference when they come within the established age limit and are able to pass a satisfactory professional and physical examination. The value of the aphorism "In time of peace prepare for war" has received additional support during our recent experience. This preparation should include a corps of trained medical officers larger than is absolutely necessary for the army on a peace basis, and systematic instruction in military medicine and hygiene for the medical officers of the national guard as well as for those of the regular army; also instruction of line officers in the elements of hygiene and especially in camp sanitation. It should also include the establishment of camping grounds in various parts of the country, having an ample supply of pure water, a proper system of sewers, etc. If our volunteers
could have been assembled in such camps during the late war, a saving in lives and money would have resulted which would, without doubt, have demonstrated the economy of such preparation for war in time of peace."

In addition to his onerous official responsibilities, Surgeon-General Sternberg had a great deal to bear during the Spanish-American war in the way of abusive newspaper criticism. It is certain now, as we maintained at the time, that he managed the affairs of his bureau with intelligence, skill, and devotion to the public interests. Far from deserving rebuke, he has earned the gratitude of the nation.

SUDDEN DEATH AND THE ERECT POSTURE.

Probably most of us have been conscious at times of a feeling akin to faintness on suddenly assuming the upright posture after kneeling, stooping, or even sitting, and it is a matter of common belief that for a very sick person to assume that posture is to incur the risk of syncope, to say the least, and that this is especially true if the person has lost a considerable amount of blood. Quite in keeping with this idea is the general practice of laying a fainting person on the back, raising the foot of the bed in cases of post-partum hemorrhage, and suspending the patient by the feet to avert threatening death by the overaction of an anesthetic.

It is assumed that in all these conditions anæmia of the brain is at the bottom of the trouble. The assumption is plausible, and, granted that it is correct, the treatment is logical. But the medical science of the present day is not satisfied with plausibility; it demands certainty. It must be admitted, therefore, that Dr. Paulesco, of the physiological laboratory of the Sorbonne, has made a notable contribution to our exact knowledge by his experimental researches into the mechanism of sudden death following on the assumption of the erect posture. The concluding portion of his account of those investigations takes up almost the whole of the October 15th number of the Journal de médecine interne.

We gather that Dr. Paulesco finds that the assumption of the upright posture is pretty sure to cause sudden death if any one of the three following conditions is present: A notable loss of blood, restriction of the arterial supply to the brain by ligation of the carotids and the vertebrals, and anæsthesia to the degree of abolition of the palpebral reflex. Essentially, all these three resolve themselves into one, anæmia of the brain, for it has been shown that profound anæsthesia is accompanied by cerebral anæmia. It is by the sudden increase of this anæmia that the brusque assumption of the erect posture is prone to give rise to speedy death. It is an interesting fact that, as Dr. Paulesco points out, the respiratory activity, which is the first to come to a definitive standstill, is under certain conditions temporarily intensified by the cerebral anæmia consequent on assuming the upright posture.

AN EARLY DIAGNOSTIC SIGN OF PREGNANCY.

We cannot have too many signs to be guided by in the early diagnosis of pregnancy. One additional to those already in use seems to have been discovered by Dr. R. von Braun-Fernwald (Wiener klinische Wochenschrift, 1899, No. 10; Fortschrifte der Medizin, October 11th). On palpation, the two horns of the uterus are found altered in size and consistence. One of them appears thicker and softer than the other. The softer portion extends beyond the median line, and at its border there is to be felt a longitudinal furrow dividing the body of the organ into two unequal portions. The thick and soft parts mark the site of implantation of the ovum.

DENGUE IN MANILA.

It is reported that the epidemic of dengue which has prevailed in the northern part of Luzon for a number of months past has traveled south to Manila, and that the disease has attacked many men of the garrison. It is gratifying to know, however, that Colonel Wood-hull reports that the really severe cases have been few, and that in most instances the men attacked were simply unfitted for duty for some days.

NEW YORK'S MEDICAL ASSEMBLYMAN.

It will be good news to the physicians of New York that Dr. Nelson H. Henry has been reelected to the assembly. The medical profession ought always to be well represented in legislative bodies, and it would be all the better if their representatives were all such careful and conscientious men as Dr. Henry.

THE GASOLINE TANK OF THE POWER CARRIAGE.

The gasoline in the tank of a power carriage is reported to have exploded recently in Fifth Avenue, with the result of burning the owner severely about the face and hands. Some new danger is almost always to be expected in connection with novel devices of the kind, but, on the whole, the power carriage, whether propelled by gasoline or by electricity, is probably less dangerous than vehicles drawn by horses.

THE TARATABGAN PLAGUE OF MANCHURIA.

In the Marine-Hospital Service Public Health Reports for November 3d we find an account of the existence for the last ten years of a disease believed to be the Oriental plague in a part of Manchuria bordering on the Siberian frontier. A rodent called by the Mongolians the tarabagan (Arctomys cobuci), described as being of about the size of a large rabbit, is thought to be instrumental in
spreading the disease. The animal's flesh is eaten, and its fat is used for greasing leather. The tarabagan is not so widely distributed as the rat, but it may be quite as dangerous in conveying the plague within its habitat.

THE SOCIETY FOR THE RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.

The New York Society for the Relief of Widows and Orphans of Medical Men, which was instituted in the year 1843, is continuing its good work. We learn from the fifty-eighth annual statement that the number of beneficiaries at the present time is twenty-four, that the society's funds amount to $334,981.86, and that its annual income is $10,301.59.

NEWSPAPERS AS AN INFECTIVE FOCUS FOR EPIDEMIC SUICIDE.

A local newspaper records the suicide of a fourteen-year-old girl in Washington because she was unable to learn Latin, though a bright and promising pupil in other studies. The method employed was the drinking of carbolic acid. On this it is remarked: "The occurrence has created considerable interest here, for carbolic-acid suicides, which are so common in New York, are almost unknown here. The newspapers gravely discuss the 'coming to Washington of the carbolic-acid epidemic from New York,' and print cartoons of the carbolic-acid monster." It does not seem to have occurred to these apter newspapers which "print cartoons of the carbolic-acid monster" that they are as guilty of aiding and abetting the introduction of this "carbolic-acid epidemic" to Washington as are the newspapers here with regard to its prevalence in New York. The infection of "suggestion" is spread by newspaper reports of such occurrences. Suicidal mania is often epidemic; but the true policy toward all epidemics is isolation, not dissemination. Every newspaper that scatters broadcast the accounts of such acts is as guilty of endangering the welfare of the community as would be a person who deliberately sent a yellow-fever or plague patient to wander forth among the populace.

"CHRISTIAN SCIENCE" AND VACCINATION IN GEORGIA.

Small-pox having recently made its appearance in a Georgia community, the authorities ordered the general vaccination of the people, so the story goes, but a number of women professing "Christian Science" refused to submit to the operation, whereupon some of them pleaded guilty to disorderly conduct and were fined or imprisoned, but the imprisonment was in their own homes with a sentinel in front. Thus was the rigor of the law tempered by chivalry.

THE PLAGUE IN THE HARBOR.

There seems to be little room for doubt that the steamship J. W. Taylor, which reached the New York quarantine station from Santos, Brazil, last Saturday, really had two of her company affected with the bubonic plague, although as yet the bacteriological examinations have not shown the presence of living germs in the pus taken from their buboes. The newspapers had had reports of the presence of the disease in Santos, but, as we stated in our issue for October 28th, it was not noted in the Marine-Hospital Service Health Reports for the week ending October 20th. It appears now, however, that Surgeon-General Wyman had information that the disease was suspected to be present or to have been present in Santos, and that on the strength of that information he warned port officers to be particularly alert in examining vessels from that region. This warning has enabled the health officer of the port of New York to take such action as is well-nigh certain to prevent the disease from reaching the city. There is, therefore, no occasion for alarm.

THE FUNDAMENTAL PRINCIPLE OF SUGGESTION.

There are two kinds of ideas we are prone to accept and believe—first, those that we wish to believe, and, secondly, those which we have been prepared to believe by the previous impact of external impressions upon our subconsciousness. The last statement enunciates the fundamental principle of suggestion, which is well exemplified in the following words from a novel entitled The Honorable Peter Stirling. Therein (page 231) we read: "The successful orator is the man who imposes his frame of mind on the audience. We call it 'saying what the people want said.' But many of the greatest speakers first suggest an idea to their listeners, and when they say it in plain English, a moment later, the audience say mentally, 'That's just what we thought a moment ago,' and are convinced that the speaker is right."

THE HOSPITAL SHIP MAINE.

It is learned that an entertainment recently given by Americans in London, organized by Mrs. James Brown Potter, was the means of adding $10,000 to the fund for fitting out the hospital ship Maine. Such manifestations of international good feeling, fortunately, are growing more and more common.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported for the two weeks ending November 18, 1899:

-| Diseases         | Week ending Nov. 11 | Week ending Nov. 18 |
--|------------------|---------------------|---------------------|
| Typhoid fever    | 126                 | 17                  | 67                  | 28                  |
| Scarlet Fever    | 105                 | 10                  | 36                  | 10                  |
| Cerebro-spinal meningitis | 0      | 9                   | 0                   | 2                   |
| Measles          | 262                 | 12                  | 248                 | 12                  |
| Diphtheria       | 248                 | 10                  | 274                 | 10                  |
| Oroup            | 11                  | 10                  | 15                  | 9                   |
| Tuberculosis     | 172                 | 148                 | 125                 | 151                 |
| Small-pox        | 1                   | 0                   | 0                   | 0                   |
| Chicken-pox      | 15                  | 1                   | 19                  | 0                   |

The State Board of Charities and the Dispensaries.—It is announced that a committee appointed to draw up a set of rules for the government of dispensaries has reported a set providing that in every dispensary there shall be displayed a notice to the effect that the institution is for the benefit solely of persons unable to pay
for medical attendance, and that clinical instruction may be given, but patients need not submit to examination, etc., for the mere purpose of such instruction.

**Marine-Hospital Service Health Reports.**—The following cases of small-pox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending November 17, 1899:

**Army Intelligence.**—**Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 11 to November 18, 1899:**

| DARNALL, Carl R., First Lieutenant and Assistant Surgeon, United States Army, will proceed to Governor's Island, New York, for temporary duty. |
| FISHER, Henry C., Major and Surgeon, United States Volunteers, will proceed by the transport Logan to Manila and report to the commanding general, Department of the Pacific, for assignment to duty. |
| JORDAN, Arthur, Acting Assistant Surgeon, will proceed to Seattle, Washington, for duty on the transport Garrone, during the voyage of that vessel to the Philippine Islands. |

**Marlow, Charles, First Lieutenant and Assistant Surgeon, United States Army, will report for duty with troops on the transport Leelanau, during the voyage of that vessel to the Philippine Islands.**

**Raymond, Henry L., Major and Brigade Surgeon, will proceed to San Francisco in charge of the sick enlisted men on the City of Puebla.**

**Stark, Alexander N., Captain and Assistant Surgeon, is granted leave of absence for one month to visit the United States, with permission to apply for an extension of one month.**

**Naval Intelligence.**—**Official List of Changes in the Medical Corps of the United States Navy for the Two Weeks ending November 18, 1899:**

| BRODICK, R. G., Passed Assistant Surgeon. Placed on the retired list of officers of the navy from November 11, 1899, under section 1453, Revised Statutes, for incapacity incurred in the line of service. |
| CLEBORNE, C. J., Medical Director. Placed on the retired list of officers of the navy from November 10, 1899, under section 1453, Revised Statutes, for incapacity incurred in the line of service; with the rank and three fourths the sea pay of the next higher grade under section 11, navy personnel law. |
| CRANDALL, R. P., Passed Assistant Surgeon. Ordered to the Constellation. |
| ODELL, H. E., Assistant Surgeon. Appointed from November 8, 1899. |
| ROSENBLEUTH, J. C., Passed Assistant Surgeon. The sick leave granted him is extended two months. |
| TAYLOR, J. S., Assistant Surgeon. Appointed from November 10, 1899. |
| WILSON, G. B., Passed Assistant Surgeon. Detached from the Constellation and ordered to the Dixie. |
| YOUNG, L. L., Passed Assistant Surgeon. Placed on the retired list of officers of the navy from November 10, 1899, under section 1453, Revised Statutes, for incapacity incurred in the line of service. |

**MONDAY, November 27th:** Medical Society of the County of New York; Lawrence, Massachusetts, Medical Club (private); Cambridge, Massachusetts, Society for Medical Improvement; Baltimore Medical Society.

**TUESDAY, November 28th:** New York Dermatological Society (private); Metropolitan Medical Society.
BIRTHS, MARRIAGES, AND DEATHS.—LETTERS.

New York (private); Buffalo Academy of Medicine (Section in Obstetrics and Gynecology); Richmond, Virginia, Academy of Medicine and Surgery.

Wednesday, November 29th: Auburn, New York, City Medical Association; Medical Society of the County of Tompkins, New York (semiannual); Berkshire, Massachusetts, District Medical Society (Pittsfield).

Friday, December 1st: Practitioners' Society of New York (private); Clinical Society of the New York Post-graduate Medical School and Hospital; Baltimore Clinical Society.

Saturday, December 2d: Manhattan Medical and Surgical Society, New York (private); Miller's River, Massachusetts, Medical Society.

BIRTHS, MARRIAGES, AND DEATHS.

Born.

Hallock.—In Fort McPherson, Georgia, on Tuesday, November 14th, to Dr. and Mrs. Harry M. Hallock, a son.

Married.

Byer—Crawford.—In Brooklyn, on Wednesday, November 13th, Dr. John Murray Byer and Miss Sadie Pearson Crawford.

Beyea—Brockie.—In New Brighton, Staten Island, New York, on Tuesday, November 14th, Dr. Samuel W. Beyea, of New Rochelle, New York, and Miss Alison Brockie.

Evans—Levering.—In Baltimore, on Tuesday, November 14th, Dr. Philip Saffrey Evans, Jr., and Miss Mary Grace Levering.

Halsey—Packard.—In Brooklyn, on Thursday, November 16th, Dr. John Taylor Halsey and Miss Mildred Wheatley Packard.

Kristeller—Vaughan.—In Brooklyn, on Wednesday, October 25th, Mr. Robert S. Kristeller and Miss Mabel Adelaide Vaughan, daughter of Dr. G. Aubrey Vaughan.

Lewis—Fowler.—In Brooklyn, on Wednesday, November 15th, Dr. Frank Newell Lewis and Miss Mary Aymer Fowler.

Owens—Miles.—In Marion, South Carolina, on Thursday, November 16th, Mr. Lamar Owens and Miss Lillian Miles, daughter of Dr. D. F. Miles.

Payne—Tuthill.—In Mattituck, Long Island, on Wednesday, November 15th, Dr. Albert E. Payne and Miss Flora E. Tuthill.

Spooner—Soley.—In Boston, on Thursday, November 29th, Dr. Henry Garretston Spooner and Miss Katherine Codman Soley.

Taylor—Cuthbert.—In Radcliffeboro, South Carolina, on Tuesday, November 7th, Dr. Joseph T. Taylor and Miss Annie W. Cuthbert.

Waters—Wilson.—In Baltimore, on Thursday, November 16th, Mr. Henry J. Waters and Miss Emily Brewer Wilson, daughter of the late Dr. Henry Parke Custis Wilson.

Wilkinson—Faulkner.—In South Greenfield, Coney Island, on Wednesday, October 25th, Dr. Richard Powell Wilkinson, of Philadelphia, and Miss Mary E. Faulkner.

Died.

Baltzell.—In Baltimore, on Wednesday, November 15th, Mrs. Elizabeth Farmum Baltzell, wife of Dr. William Hewson Baltzell, of Frederick, Maryland.

Buchanan.—In Meridian, Mississippi, on Wednesday, November 8th, Mrs. Sallie May Buchanan, wife of Dr. J. M. Buchanan.

Mauran.—In Creston, Iowa, on Wednesday, November 1st, Dr. Antoine Joseph Mauran, in the sixtieth year of his age.

Morrison.—In Baltimore, on Monday, November 13th, Dr. James M. Morrison, in the sixty-second year of his age.

Prentiss.—In Washington, on Sunday, November 19th, Dr. D. Webster Prentiss, in the fifty-sixth year of his age.

Robinson.—In Hot Springs, Arkansas, on Thursday, November 9th, Dr. Samuel Quincy Robinson, United States Army.

Rosenbaum.—In New York, on Monday, November 13th, Mr. Jacob H. Rosenbaum, father of Dr. Solomon N. Rosenbaum.

Seahle.—In New York, on Wednesday, November 15th, Dr. Dayton Wyckoff Seahle, in the sixty-second year of his age.

Smith.—In Jersey City, on Sunday, November 19th, Dr. Matthew J. Smith, in the fortieth year of his age.

LETTERS TO THE EDITOR.

THE ETIOLOGY OF BERIBERI.

New York, November 19, 1899.

To the Editor of the New York Medical Journal:

Sir: In spite of Osler's opinion as to the epidemic and endemic character of beriberi, it certainly is not epidemic in Japan, nor is it even endemic (excepting in the rainy season—June, July, and August), Wernicke and Baclz to the contrary notwithstanding. The rice and anemia etiologies is a very old one, but has nothing in its favor. The mountaineers of Japan, who are, as everybody knows, proverbial gluttons as regards rice—eating, in fact, nothing else—are free from beriberi; of course, if they descend into the depressed centres, where the permanent presence of poisonous gases gives the disease the appearance of periodical endemicity, they share the common lot. Let me observe that this medium does not produce the disease at once, and that its influence becomes manifest only after several months. There is to the freedom of mountaineers from kakke only one exception that I know of, and that exception proves the rule. Shinano is situated eight hundred metres above sea level, and there kakke occurs; but this same Shinano is surrounded again by higher hills, so that it is really a cup from which the gases can not escape. There is rarely or never a diastolic murmuru in beriberi because the heart fills insufficiently. A prolonged first sound is usual. The swollen abdomen is also usual, and it is that which has led some observers to assume a polysarcous form of the disease; but, on puncturing the wall, the swelling soon disappears. We must consider that the respiration of the beriberi patient is necessarily abdominal. The rotund abdomen is sometimes due to circumscribed oedema, but such cases are fatal. Quick recovery in all cases, as soon as the pa-
SPECIAL ARTICLES.

THE LAW IN ITS RELATIONS TO PHYSICIANS.
By ARTHUR N. TAYLOR, LL. B.

Privileged Communications.
(Continued from page 765.)

Relation of Physician and Patient must Exist to Create Privilege.—Having learned that the physician to whom the confidential communications were made was duly licensed and authorized to practise medicine and surgery, it next becomes pertinent to determine whether or not the relations existing between the patient and the physician to whom the communications were made were of such a character as to bring such communications within the protection of the law.

The general proposition that because one is a licensed physician and surgeon he is incompetent to testify regarding the condition in which he found a certain person without that person’s consent is too absurd to require refutation; this privilege must be based upon a relation of confidence similar to that of physician and patient, and unless such relation, in fact, exists at the time the information is obtained there is no privilege; * nor will the court presume the existence of such confidential relations. The party invoking the aid of the law must show that the relations which existed between the physician and himself were of the confidential nature contemplated by the statute. †

In order to constitute the confidential relation of physician and patient it is not essential that the physician should have been called or employed by the patient himself; the legal effect is quite the same whether the physician is summoned by the patient himself, by the patient’s attending physician, by friends of the patient, or even by strangers. * It therefore logically follows that where the defendant in a suit for personal injuries sends his physician to the plaintiff to make an examination for the purpose of testifying as to the plaintiff’s condition, and the physician, instead of simply making the examination for the purpose intended, undertakes the treatment of the plaintiff, the relation of physician and patient immediately arises, and the physician becomes incapable of disclosing the information obtained. † In the case of Freer vs. Market Street Cable Railway Company, † the plaintiff testified that defendant’s physician called upon her several times and prescribed for her. The doctor, when questioned upon the subject, failed to remember whether he did or did not prescribe for her. Thereupon the plaintiff’s counsel asked him the following question: “It was during this time that you were making these visits and prescribing for her that you obtained any knowledge that you have of her case?” to which the physician answered, “Yes, sir; that is all, except conversations with Dr. ——.” The court was of the opinion that even though the physician was sent for the sole and exclusive purpose of examining the plaintiff to enable him to disclose her condition, yet by ‘visiting and prescribing for her’ the confidential relation of physician and patient was created, which would preclude the disclosure of any information gained while making such visits. And so in the case of People vs. Murphy, * where the public prosecutor selected a physician and sent him to examine a woman upon whom an abortion had been performed, for the apparent purpose of obtaining evidence, and the physician, in treating the patient professionally, he was not permitted to give any information obtained while so treating her.

Where, however, a physician calls upon a person and examines him only for the purpose of information, and it is understood that the purpose of the call and examination is not for professional treatment, no question of privilege can be successfully urged. || Therefore, where a physician, at the request of the prosecuting attorney, entered the cell of a prisoner and had a talk with him for the purpose of determining his mental condition, but rendered to him no medical assistance or advice, the physician’s observations were properly admitted in evidence. † And so, when a physician, at the request of the prosecuting attorney, examined a prisoner while in jail for the purpose only of determining whether or not he was afflicted with a venereal disease, the court held that no confidential relation existed, and that the information gained might properly be disclosed. † And for a like reason it is held, where two physicians, not attending upon the testatrix personally, are taken to her bedside for the purpose of determining her mental condition, and while there witness the execution of her will, that no professional relation is thereby created between the testatrix and witnesses, and that they are competent to disclose what they learned at the examination. One of the physicians, in answer to questions propounded to him at the trial, said

* Jacobs v. Cross, 19 Minn., 523.
‡ Renihan v. Dennin, 106 N. Y., 573.
° People v. Murphy, 101 N. Y., 126.
∥ Nesbit v. People, 19 Colo., 441, 36 Pac. Rep., 221.
that he was not testatrix's physician or surgeon at the time, and didn't prescribe for her; was not called, as he understood it, to prescribe for her; that he was not her family physician; that he made a charge for making the examination upon his books to the attorney who prepared the will and was present at the examination; that he made the examination the same as he always did when called upon to examine a person with regard to sanity, and after the examination the will was at once executed. The other physician's statement of the purpose of his visit was in legal effect much the same. In considering the admissibility of the evidence of these physicians the court said: "In the present case the physicians were not called to prescribe for the deceased or to advise as to professional treatment; nor did they so prescribe or advise. If the deceased at the time of their visit had been in great need of good medical advice, and they had given no advice, they would not have been chargeable with malice or neglect of duty; because they were not under any obligation to advise or to prescribe. Any advice or prescription would have been an improper act, because they were not the attending or consulting physicians, and they were under no obligation to her. If they had conversed with her as to her health, then, possibly, she might have conceived the idea that they were consulting physicians. And if, in such mistaken belief, she had stated anything as to her health, very possibly that might have come within the prohibition of this section. But . . . there is no reason to believe that she thought them to be consulting physicians, or recognized them to be anything more than proper witnesses to her will." *

The proper test, it seems, to apply in determining the competency of the physician to testify, is whether he met the party professionally or non-professionally at the time the information in question was obtained.†

Thus, when a physician offered to give evidence as to the mental capacity of the deceased, and this evidence was objected to upon the ground that he had been the attending physician of the deceased, the court, upon being shown that the knowledge regarding which the physician proposed to testify was not obtained while acting in that capacity, properly permitted the physician to testify.‡ And upon the same principle a physician who had attended the deceased was permitted to state what he had observed relative to deceased when he called upon him for the purpose of collecting some money which was due for professional services. The physician was also permitted to testify that he met deceased in the road near his home, and that the old gentleman did not know him, and asked who he was." The physician must, however, be able to separate the knowledge which he acquired from the patient while attending him in a professional capacity from that which he obtained upon meeting him in a non-professional way, otherwise he will not be permitted to testify as to the latter.¶

In the case of the Colorado Fuel and Iron Company vs. Cummings,* the defendant, the Colorado Fuel and Iron Company, together with a certain railroad com-

¶ In re Darrah, 52 Hun, 391.

pany, had established a hospital for the use of the two companies, which was supported by contributions from the employees, certain amounts being deducted from their monthly wages for that purpose, the general contribution being termed the "hospital fund." The plaintiff, who had been injured while in the course of his employment with the defendant, was taken to this hospital and attended by a physician who was employed by the company and received his salary from it, probably from the "hospital fund." This physician offered to testify regarding the plaintiff's condition, but his evidence was refused. The court, in considering the question of whether or not the relation of physician and patient existed between the plaintiff and witness, said: "We are, however, entirely satisfied that the circumstances under which the doctor was employed and the relation existing between the company and its employees and the doctor were such as to put the physician and the plaintiff directly in the relation of doctor and patient. The plaintiff's contributions may have been slight, but the circumstances of the situation were such as to lead him to put himself implicitly under the care of the surgeon and to trust himself in his hands for care to the same extent and under the same circumstances as though he had sent out for another physician and put himself directly in his charge."

From this case an inference seems deducible that the confidential relation of physician and patient can not exist when the physician is wholly paid by a third party. However justly such an inference may be drawn from the opinion of the learned court in this case, it is apprehended that such a statement would not be correct law.

The law is probably better illustrated in the case of Grossman vs. Supreme Lodge of Knights and Ladies of Honor.* In this case the patient was at a hospital and her regular attending physician was a Dr. W. A Dr. N. was called as a witness to testify to the patient's condition, but his evidence was objected to upon the ground that the knowledge he possessed was privileged. In order to determine the relation existing between the patient and Dr. N., he was permitted to state his connection with the hospital and the circumstances under which he met the plaintiff. He stated that he and Dr. W. had charge of different wards in the hospital and that he and Dr. W. made the rounds of the hospital together, and generally examined the cases together; that he was not the physician attending the patient, although he partly attended her. Referring to the patient, he said: "I went with Dr. W., who was the attending physician. We generally tried to confirm diagnosis. I went there to find out the condition of the patient, and the ailments." And again he said: "I went there just out of curiosity to acquire information in interesting cases." And later in his examination he said that when Dr. W. went to examine the patient he went with him "and assisted him in making the examination." Regarding the admissibility of Dr. N.'s evidence of the condition of the patient, the learned court said: "We think the court properly held that the witness was disqualified. 'To bring the case within the statute it is sufficient that the person attended as a physician upon the patient, and obtained his information in that capacity.' † Whether the witness was actuated by curiosity or a higher motive makes no

† From Reinhart vs. Dennin, 103 N. Y., 573.
difference. His own admission that he attended the patient, although he qualifies the statement by the use of the adverb "partly," suffices to establish the existence of the professional relation which debars him from disclosing what he learned of her condition under the circumstances."

A jail physician, it seems, is also incompetent to testify as to the condition of a prisoner whom he has attended in a professional capacity; but unless it can be shown that the information he offers to disclose was obtained while attending such prisoner professionally he will not be prevented from testifying.

Whether or not the professional relation of physician and patient exists to such a degree as to protect the communications made to the physician where a third party comes to him and makes disclosures for the purpose of getting medicine or a prescription for the patient is a question that is largely dependent upon the circumstances of the particular case. In an early New York case † the defendant repeatedly applied to a physician for drugs to produce an abortion, and upon one occasion told him the name of the female for whose use the drugs were desired. The physician was permitted to disclose the subject of these interviews, the court expressing its opinion as follows: "The witness (the physician) I think was not privileged. It is very doubtful whether the communications made to him by the defendant can be considered as consulting him professionally within the meaning of the statute." And so, in the case of Babcock vs. People, ‡ a physician was permitted to testify that defendant came to him and told him that he wanted some medicine for a certain young lady who had taken a cold and was suffering from suppressed menses, and that subsequently, in about a month, the defendant returned the medicine and said it was for his wife and was not given because she was pregnant. The court said: "The defendant was not consulting him (the physician) for himself, nor does it appear that he was representing any one else who needed or desired medical assistance." If, however, a third party appears before a physician and confidentially discloses to him the condition of a patient and procures the physician to undertake the treatment of such patient, the relation of physician and patient exists in its full sense, and the information conveyed through the third party is as adequately protected as through communications by the patient direct.‖

It has been observed that the confidential relation of physician and patient is not dependent upon the employment by the patient, but that such a physician may be called by another. Similar to this is the rule that a physician who is called by the attending physician as consultant is within the law and not permitted to disclose knowledge gained in the course of such consultation.|| The partner of the attending physician also comes within the rule and is not permitted to disclose knowledge imparted to him by the attending physician.

Justice Berkshire, in considering a question of the sort, said: "Dr. L. (the partner) comes clearly within the spirit, if not the letter, of the statute. He was the partner of Dr. W. (the attending physician). They were in active practice, occupying the same office. The business of the one was the business of the other; when necessary, it was the duty of one to consult with the other, and in the absence of the one who was giving special attention to a patient, it was proper for the other, if not obligatory on him, to take his place." In this case the court, after stating that the information possessed by Dr. L. was obtained while the patient was at the firm's office to consult Dr. W., expressed itself positively that to have permitted Dr. L. to disclose this information "would have been a perversion" of the statute. It seems, however, that a physician merely having office privileges with the attending physician, but not interested in his business, does not come within the law and will be permitted to disclose information imparted to him by the other's patients.†

Nor does the relation of physician and patient exist as contemplated by the law when the physician performs an autopsy, as a dead man can not be considered a "patient," "but is a mere piece of senseless clay which has passed beyond the reach of human prescription, medical or otherwise." Therefore information disclosed at such autopsy is not privileged.‡

The statutes, in designating to what relations the privilege shall extend, more frequently use the expression that no person authorized to practice "physic or surgery" shall be permitted to testify, etc. Such a designation as this is restricted to a physician or surgeon and is not construed to include a dentist; for while the duties of a dentist include to a very limited extent those of a surgeon, yet it has been held that a dentist is not, in law, to be considered a surgeon; therefore communications made to him will not be privileged.||

(To be continued.)

Pith of Current Literature.

The Therapeutics of Kola.—Dr. Charles C. Yarbrough (Journal of the American Medical Association, November 4th), in a paper presented to the Columbus meeting, says that among the new therapeutic applications of kola, where its success has been particularly noteworthy, is its exhibition in the treatment of that obdurate disease of childhood—pertussis. Blocker reports that he has used it in a large number of cases with surprisingly good results—the attack being cut short and the child's condition rapidly improved. Its influence has been so grateful in a large number of cases that further trial along this line to establish its true value is called for.

In asthma, kola has proved itself to be peculiarly beneficial, relieving many cases, some permanently, where other medicinal agents have failed to give good results.

On the hypothesis that asthma is a true neurosis of the respiratory apparatus, it seems obvious that kola

---

† Kendall vs. Grey, 2 Ilit., 300.
should be of material service in that affection. It must be admitted that there are a variety of causes that will produce an asthmatic condition, but the manifestations of the disease are always nervous in character. Kola has been employed with signal success in some very obstinate cases of asthma, and this fact entitles it to be considered in formulating a treatment for this dyspnoea. At best, asthma is very unsatisfactory to treat, and any drug promising to give prolonged relief to the distress of an asthmatic patient should have a careful trial. There are some forms of asthma where kola, or for that matter any other medicinal treatment, will be useless; for example, those cases due to pressure by a tumor on the pneumogastric nerve. Because kola acts well in a number of cases of asthma, it must not be taken for granted that it is a specific for that disease, and, if it fails in some instances, it does not follow that it is valueless in all. This is an axiom that should be applied to all drugs in their respective therapeutic applications.

Kola is a decided diuretic. It acts more energetically on some people than it does on others. In the author's experience it has proved to be very prompt and satisfactory as a diuretic, even more so than caffeine and digitalis combined. There are indications that strongly suggest some peculiar direct action on the kidney, although its action is largely indirect, by increasing the blood pressure. Being a reliable diuretic, it is highly serviceable in Bright's disease, cardiac and renal dropsy, rheumatic and rheumatoid conditions, and in all cases where a stimulus to diuresis is indicated, and particularly in those cases characterized by atonic conditions.

As a cardiac tonic, it ranks well with digitalis, and, like the latter, causes an increase of urine. Kola, unlike digitalis, has no cumulative action; hence it is a good substitute for digitalis and may be used whenever the latter is indicated, or the two may be advantageously combined. Kola is, then, of service in cardiac diseases, in cases of shock with collapse, delirium tremens, etc.

Melancholia is another morbid manifestation in which kola gives admirable results. There have been cases, apparently irreducible, that have been entirely cured by the timely use of kola. The value of kola in this disease is gradually becoming more widely and better known and, as a result, it is now used in nearly if not all of the leading institutions for the treatment of mental diseases.

In alcoholism and morphinism, two deplorable conditions, the effects of kola as a stimulant and supporter are of great service in sustaining the system against shock from gradually reducing or interdicting entirely the use of alcohol or morphine, respectively. It is true that the cure of these habits depends largely on moral suasion and a determination on the part of the victim to rid himself of his vice, but a stimulant whose effects will replace those of the irresistible habit drug without itself producing a depressed and vitiated condition of the system, is of immense value in tiding the individual through the ordeal of breaking away from the influences to which his system is so accustomed.

Kola is of value in combating and preventing surgical shock. Administered before and after a surgical operation, its power of conserving strength and exerting a tonic influence on the nervous system will certainly render the patient less liable to collapse. It has been used by some of our leading surgeons for this purpose and invariably with success.

Uterine inertia, when due to nervous exhaustion or occurring in weakly, debilitated women, has been found to be amenable to the action of kola. Kola is also useful in normal parturition to sustain the strength of the patient and stimulate the uterus to its best action.

The Treatment of Post-partum Haemorrhage.—Dr. J. Z. Currie (Boston Medical and Surgical Journal, November 10th) thus summarizes a paper read to him before the Cambridge Society for Medical Improvement and the Boston Gynecological Society: 1. A knowledge of the source of the haemorrhage is necessary to insure intelligent action. 2. All rents, when easy of access, should be repaired at once. 3. If the body of the uterus is contracted and bleeding excessive, and in all cases of haemorrhage following placenta previa, the whole cavity should be tamponed at once. 4. If this is not successful, or if the haemorrhage is constant and not excessive, secure the bleeding vessels and, if possible, repair the injury. 5. If atony exists and haemorrhage is not excessive, use external and bimanual compression of the uterus, followed, if necessary, by hot water, vinegar, or acetic acid. 6. If not successful, or if atony exists with excessive haemorrhage from the outwat, tampon at once after using hot water. 7. Give morphine hypodermically to check the haemorrhage, and stimulants, strychnine and aut infusion, to overcome the effects of the haemorrhage. 8. To prevent anaemia, use saline solution, preferably per rectum or hypodermically. Saline solution may be used by infusion also, if necessary.

The Penetration of Bacteria into Eggs.—Bucco (Reforma medica, October 3rd, 4th, 5th, and 6th; British Medical Journal, October 28th), as the result of a series of experiments on this point, finds that many pathogenic bacteria, for example, Staphylococcus pyogenes, Loefler's bacillus, etc., penetrate within the egg boiled at 100° C., and are arrested at the albumen, but in some cases (Proteus vulgaris, Bacillus indicus, Bacillus diptheriae) reach as far as the yolk. Eggs cooked at 134° C. resist much longer. It is also found that many bacteria are able to penetrate the raw egg. The Bacillus subtilis is unable to enter either the raw or cooked egg. The Bacillus diptheriae, although able to enter the egg cooked at 100° C., can not penetrate the raw egg. The typhoid bacillus is able to enter the egg in twelve hours, and keeps its vitality for four or five days. Seeing the kind of material and the places in which eggs are stored, these researches showing that eggs offer no insuperable barrier to the entrance of microbes have some importance from the sanitary point of view, and form an additional argument for greater cleanliness in the storage of these valuable articles of diet.

The Therapeutics of Theobromine.—M. Lemoyne de Vemon (Gazette hebdomadaire de médecine et de chirurgie, October 1st), in his thesis regards theobromine as a trustworthy and powerful diuretic, acting directly upon the kidneys, imposing no effort upon the heart, but rather relieving that organ by causing a rapid diminution of oedema. Theobromine also causes the disappearance of toxic dyspepsia and calms precordial distress. In vascular diseases, digitalis has its contraindications and causes of failure, the principal of which is myocarditis. Though par excellence the medicament in asystolia it may fail from the very first. Then theobromine should be substituted for it. This drug occasions no evil effects in cardiac
patients. When to any cardiac lesion is added renal trouble, and particularly cardio-renal sclerosis, the general effects of digitalis, and especially its diuretic properties, become unreliable, and are nearly always insufficient. Theobromine should in such cases be substituted for it insures diuresis, without detriment to the kidney, and supports the heart by disencumbering the peripheral circulation. Nevertheless, if digitalis is powerless against edema it can aid occasionally in regulating the heart, and it should be given in a moderate dose when signs of failing are present. In the course of renal insufficiency to combat uraemia, imminent or actual, more certain success is likely to be attained if to the local or general deprecation to disembarrass the kidney is added the employment of theobromine to awaken the functional activity of the renal epithelium.

Peculiar Result of Attempted Self-induced Abortion.—The Indian Medical Record for October 4th, citing the Canada Lancet for unnamed date, says that in the Surgical Section of the Ontario (Canada) Medical Association, Dr. Harrison, of Selkirk, reported the case of a woman with a large family, who, being again pregnant two months and a half, was advised by a neighbor to produce an abortion, saying that it was a very easy thing to do and no trouble arose other than from an ordinary monthly sickness. A glass stylet penholder was passed blunt end foremost, but slipped from the woman's grasp and was lost to her touch. On examination, Dr. Harrison could find no rent or tear of any kind either in the vaginal walls or in the walls of the uterus. Even after putting the woman under chloroform the stylet could not be found. The woman was most positive that it was there, and that it had been passed blunt end foremost. An exploratory abdominal operation was performed, and the stylet was found in the region of the spleen with the point almost impinging upon the diaphragm where the heart lies on that muscle. The woman recovered with nothing worse than a stitch abscess.

The Relation of Heart Disease to Pregnancy.—Dr. Adam H. Wright (American Medical Quarterly, September) summarizes his paper on this subject as follows: 1. A woman having a heart lesion which is compensated should not be prevented from marrying. 2. Abortion should not be induced on a woman with heart disease unless very serious symptoms are present. 3. Premature labor should seldom or never be induced on account of heart disease. 4. Mitral stenosis is the most serious heart lesion during pregnancy and labor; aortic stenosis comes next; then, probably, aortic incompetence. Mitral insufficiency is the least serious lesion. 5. Treatment during pregnancy. Administer the following according to indications: Strychnine, digitalis (or strophanthus), cathartics, nitrite of amyl, nitroglycerin, and regulate the diet. 6. Treatment during labor. Keep up the action of digitalis (or strophanthus), especially during first stage. Give strychnine and stimulants if required, and chloroform. As soon as the first stage is completed deliver with the forceps. 7. Watch the patient carefully during the third stage (the most dangerous time) and for some days after.

A Crowbar Traversing the Vertical Diameter of the Abdominal Cavity, with Survival for Three Weeks.—Dr. A. C. Miller (Edinburgh Medical Journal, October) records this case and says that the manner in which this accident occurred was very peculiar. The patient, a strong young Irishman aged twenty years, had been engaged "dressing" a railway embankment, in course of construction. Standing on the outside ledge, he was performing the duty by means of a long, pointed crowbar, when, suddenly, the instrument missed its billet, and the poor fellow lost his balance. Letting go his hold of the iron, the latter, turning heel downward in its course, first reached the bottom of the declivity, stuck fast in the ground, and presented its pointed extremity to the navy as he tumbled after. The point entered the right thigh in front and emerged below the right shoulder posteriorly. A companion who witnessed the occurrence rushed to the patient's assistance and with some difficulty succeeded in withdrawing the crowbar: The patient was then conveyed to hospital, partly by locomotive engine and partly by trap, for a distance of eighteen miles. On admission he was found to be very collapsed; pulse weak and rapid, face cyanosed, extremities cold. Stimulants were administered in hot milk. Hot bottles were applied, morphine was injected hypodermically, and soon the patient recovered to the extent of permitting a detailed examination to be made. The point of the crowbar had entered about four inches below the line of junction of the thigh to the pubis. The course was through the subcutaneous tissue of the limb, under-neath Poupart's ligament, and through the abdominal cavity. The wound of exit was situated about an inch and a half below the angle of the right scapula. There was not much bleeding from the wound of entrance. The femur was uninjured, and the patient could flex and extend the thigh without difficulty. The femoral artery could be detected feebly pulsating on the outside of a swelling underneath Poupart's ligament. This swelling gurgled distinctly on pressure. The tenth and eleventh ribs were found to be fractured and comminuted, and a splinter from the tenth had been thrust upward so as to penetrate the pleural cavity. There was considerable oozing from the thoracic wound. The tissues around were empysematous, and air passed freely in and out of the aperture. The wound was valvaral; that is to say, the opening in the skin was at a higher level than the injured ribs, but on drawing the skin and subcutaneous tissue downward, the fractured bones could be easily seen by electric-lamp light. The splinter that caused the pleural wound was caught by forceps and removed. For an hour or two after admission there was considerable disturbance in the respiration, and aceration of the blood seemed to be carried on with difficulty. The pulse was extremely weak and irregular, and the face was deeply cyanosed. By and by, however, the respiration and circulation became quiet and regular. The patient slept at intervals, and in the evening stated that he felt no discomfort whatever. The temperature was 102.3° F. Eighteen ounces of clear, healthy urine were drawn off; one fourth of a grain of morphine was administered hypodermically every four hours. Toward morning on the following day (25th) vomiting set in. The patient said he was relieved by the emesis. The vomited matter consisted of bile-stained fluid, tinged also, slightly, with blood, and it was sour-smelling. The temperature fell to 99° F.; the pulse to 100. Flatus passed freely. The wounds looked healthy, and, after being thoroughly irrigated, were stuffed with iodoform gauze.

For several days the patient remained in much the same condition, vomiting being almost incessant, relieved occasionally by ice and sometimes by the application of a sinapis to the epigastrium. Morphine was
given less frequently. The urine for the most part passed voluntarily and in normal amount. Rectal enema gave no result. Then tympanitic distention of the abdomen began to set in.

On the 31st of December the patient's condition became very critical. He passed a very restless night, being much disturbed with vomiting, which was of a very offensive character, and resembled chopped parsley in appearance. Temperature subnormal and extremities cold. Pulse small, slow, and compressible. Thoracic wound healthy. Wound in thigh dry and gangrenous. For twenty-four hours the amount of liquid ingested was seventy-two ounces. During the same period twenty-eight ounces of fluid were vomited, and thirty-five ounces of urine passed. The bowels moved on this day for the first time since the accident—an interval of seven days. The abdominal distention became less, and the vomiting not so constant. In the general condition, too, improvement followed. The facies became less anxious, the pulse quieter and more regular and full, and the skin rose to a pink. But later, again, the bowels became very troublesome. The stools were peaty in character, occasionally interspersed with air bubbles. Bismuth, chalk, opium, and acetate of lead were given in various combinations to counteract the diarrhoea, but with only intermittent success. The vomiting for a time disappeared after the occurrence of the diarrhoea. The pulse became small, rapid, irregular, and feeble. Temperature pursued a fairly normal course. The patient's features became more and more anxious, emaciation progressed, and the abdominal distention increased. The thoracic wound discharged a large quantity of pus, and daily irrigation with carbolic solution was carried out. A drainage tube was inserted. The femoral wound became healthy and tended to granulate.

On January 5th the patient began to expectorate a peculiar slaty-greenish spit, tinged at times with blood. He complained of pain in the right side, in the region of the wound; and it was noted that he felt much relieved after each dressing, when large quantities of pus were got rid of. His face and nose, eyebrows, and forehead became covered with a thick herpetic eruption.

Throughout the patient was very keenly conscious, and was distressed chiefly by the persistence of the abdominal swelling. Turpentine internally, and externally combined with fomentations, was employed for the reduction of the distention, but without effect. There was no tenderness on pressure. On the 7th the protrusion of bowel into the track of the femoral wound could be distinctly palpated as a hernia, and was easily reducible. On the 8th the patient had a syncopeal attack, after which his condition remained critical from weakness. He ingested large quantities of milk, but owing to the recurrence of vomiting, it was deemed advisable to a large extent to substitute alcohol and ice. Exhaustion daily increased. On the 11th—to indicate the intractable nature of the intestinal irritation—a large quantity of laxative was required. The patient succumbed on the 14th.

At the autopsy the following conditions were noted: Body extremely emaciated. External wound on right thigh; oblique margin four inches below pubic spine, an inch and a half in vertical measurement, two inches transversely. External wound in right infrascapular region in line with angle of scapula, occupying partly the sixth, and the seventh and eighth interspaces. Vertical measurement of wound, two inches; transverse, an inch and a quarter. On opening into the abdomen, the peritoneum was found thickened and adherent to the abdominal wall. The coils of intestine were distended and matted together. The omentum was represented by a thin membranous layer, with only traces of fat on its surface. A line of redness marked the upper line of adhesion between the coils of intestine. In the right iliac region, the bowel, peritoneum, and abdominal wall were closely adherent, and there was deep adhesion between the intestinal coils. The hernial protrusion into the cavity continuous with the external opening in the thigh consisted of small intestine glued together, and extremely difficult to separate. The funnel-shaped tube containing the hernia was wider at its proximal than at its distal end, due, no doubt, to the downward pressure of the bowel. The peritoneum was prolonged over the protruding intestine and was adherent to the muscular wall of the hernial cavity. The cecum at its upper extremity was very deeply injected. In the process of separating adhesions between the bowel and liver, a tear of the size of a threepenny piece was made into the upper wall of the duodenum, from which issued a large quantity of intensely yellow thin fluid. The liver was enlarged. On its lower aspect, in the middle line and near the external border, was a torn, ragged surface, about two inches and a half in its longest diameter—i.e., transversely to the organ. A lacercated wound, somewhat similar in size and appearance to the former, was found upon the upper external aspect of the gland. There was a wound in the thoracic wall below the insertion of the diaphragm, situated about two inches and a half external to the vertebral column, two inches in its vertical and an inch in its transverse extent. The tenth and eleventh ribs were fractured and comminuted in this situation. The right pleural cavity was found to be occupied by a large quantity of sero-purulent fluid.

The author remarks upon the extreme elasticity of the bowel as evidenced by absence of penetration. The injury to the duodenum he considers due to pressure between the weapon and the denser liver tissue, and does not think, in face of the adhesions that were forming, that it would have presented an insuperable obstacle to recovery. Toxaemia, hepatic rupture, and septic fluid in the thorax were, in his opinion, the causes of death.

The Action of Hydroxyamine on the Kidney.—Dr. G. Alonzo [Clinica medica italiana, 1898, No. 9; Centralblatt für innere Medicin, November 4, 1899] maintains that hydroxyamine produces in rabbits a true nephritis, most marked in the cortical substance. Binz found evidence of its action on the kidney only in one instance, in amounts of 0.15 of a grain to each kilogramme of the animal's weight.

End-to-end Anastomosis of the Ureter.—Dr. Dudley Allen and Dr. C. E. Briggs [Boston Medical and Surgical Journal, October 7th] relate a case of horse-shoe kidney in which a successful end-to-end anastomosis of the ureter was accomplished. One ureter having been divided, a second ureter was found during the enucleation of the kidney implanted into its substance. Inasmuch as at the time of the division of the ureter the distal end had been seized with a pair of hemostatic forceps, and thus crushed, it made the remaining portion of the ureter so short that a lateral anastomosis seemed impossible. The proximal end of the divided ureter was also cut off so high up that it was impossible to implant it into the bladder. The only thing which re-
mained was an end-to-end anastomosis. This was done with very fine catgut and a careful and accurate approximation made. The operator, fearing lest there might be leakage of urine followed by infection of the abdomen, utilized a flap from the anterior wall of the pelvis, which had been partly formed by the removal of the uterus, and drawing this upward and backward sutured it to the brim of the pelvis. By this means the abdominal cavity was entirely closed off from the pelvis, and iodiform gauze was carried through the vagina and pelvis into the retroperitoneal opening made in the operation attempted upon the kidney. Some leakage occurred shortly after the operation. The authors remark that, of course, in a case of this sort it is impossible to demonstrate absolutely the success of an end-to-end anastomosis of a divided ureter. It might be said that the patient had but one pelvis to the kidney and that all of the urine passed by the undivided ureter. It might further be said that the calibre of the ureter had been closed by cicatrization, and that a portion of the kidney which it drained had become atrophied, its function being taken up by that portion of the kidney drained by the right ureter. An attempt was made during the progress of the case to see whether on the days in which there was leakage of urine per vaginam the amount passed by bladder was less, and also whether on days when there was no leakage per vaginam the amount passed by the bladder was greater. The authors were unable, however, to satisfy themselves upon either of these points, and therefore think that it is fair to conclude that the case is one of successful end-to-end suture of a divided ureter.

Proceedings of Societies.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of June 7, 1899.

The Vice-president, Dr. Charles E. Quimby, in the Chair.

(Concluded from page 607.)

Report of Cases of Sudden Death from Pulmonary Embolism, following Injuries or Operations in the Pelvic Region.—Dr. George P. Biggs read a paper with this title. (See page 772.)

Dr. Porter expressed the opinion that many cases of sudden death, particularly those occurring soon after an operation, which had hitherto been usually attributed to cardiac trouble, were quite possibly due to the condition which Dr. Biggs had described. He referred to a case coming under his observation where death had suddenly taken place about twenty-four hours after the removal of the breast. There had been no signs of cardiac trouble prior to the operation, and none had been revealed at the autopsy. In that instance, very probably, death had resulted from a pulmonary embolism.

Report of a Case of Myotic Endocarditis.—Dr. H. M. Biggs reported the case.

Dr. Quimby thought it possible that Dr. Biggs's case belonged to a class in which suppuration occurs without the presence of pus organisms. He asked Dr. Biggs upon what grounds he assumed that an infection had occurred in this case, in view of the fact that the cavity had been so well protected, and that all efforts to find any kind of bacteria had utterly failed.

Dr. Biggs replied that his assumption had been based on the general ground that the anatomical lesions were identical with those found in infectious processes. The parenchymatous degeneration in the liver and kidney, as well as the nature of the changes in the heart, all pointed to an infection. Furthermore, we knew that occasionally organisms present in infectious processes die out. So far as he knew, such a clinical history, accompanied by such anatomical changes, could not result from chemical poisons. On the other hand, we did know that just such lesions and such a history were associated with infection, and that the organisms causing such infection might die out.

Dr. Quimby said that long before he had studied medicine he had met with an accident which had since suggested to his mind the possibility of a supplicative process from purely mechanical irritation. In attempting to close a door on a very cold day his forefinger had been injured while pulling on a glass door-knob. The wound had healed by first intention, but subsequently an abscess had developed at the site of the injury, and when this had opened, a piece of glass had escaped. Within a few months this process had repeated itself absolutely. Dr. Quimby said that in this case he was inclined to attribute the suppurative process to irritation rather than to the presence of a microorganism.

Report of Cases of Fibroid Tumors of the Uterus Complicating Pregnancy.—Dr. H. C. Cor read a paper with this title. (See page 773.)

Dr. Porter said he thought the essential point in connection with this subject was the situation of the fibroid growth. Certainly, a small fibroid growth—in fact, fibroid growths of considerable size in the upper portion of the uterus, and particularly those of the subperitoneal variety—had comparatively little bearing upon the possible existence of pregnancy. Those in the lower segment of the uterus, however, might prove very serious, and should be given due weight and consideration. In view of this possibility, operative interference should always be considered, no matter how small the growth might be. In such cases he was in favor of removing the growth without removing the uterus itself. He referred to two cases of this character, which he had presented to the society, in which pregnancy had subsequently occurred. In these the fibroids had been of the submucous variety, both being of considerable size, one having attained the dimensions of a small fetal head. In that instance the growth had protruded from the cervix, and it had been removed entire, without morcellation. In the majority of cases, however, it was better to resort to morcellation. In those cases in which the growth was subperitoneal, the operation was very simple, and even during pregnancy, if the growth were situated low down, its removal might possibly be accomplished without interfering with gestation. Of course, with the interstitial variety, where the uterine tissues were involved, the conditions were different, and there very often hysterectomy would be necessary.

Dr. William J. Chandler said that these cases should be considered from all points before an operation was undertaken. He referred to one which had come under his observation ten or twelve years ago, that of a
lady who had been married for some years, and who believed that she was pregnant. Upon examining her he found a tumor, somewhat movable, a little to the right of the uterus, which gave him the impression that the case was one of extra-uterine pregnancy. The woman had all the rational symptoms of pregnancy, and after observing her for a week or two he advised her to consult a noted obstetrician, who, being unable to form a positive conclusion, called in an eminent ovariotomist. They finally decided that there was a subperitoneal fibroid, low down, and somewhat pedunculated, and one of them almost insisted that an immediate operation was the only means of saving the patient’s life. The obstetrician, however, was in favor of waiting, and sent the case back to Dr. Chandler. That woman was delivered, in due course of time, of a healthy child, now ten or twelve years old.

The speaker said that in a case like the one he had narrated, it would certainly have been unwise to operate, as the woman had a pedunculated fibroid, which did not interfere at all with gestation. A submuco us fibroid might present more serious symptoms, but the mere presence of a fibroid in a gravid uterus did not necessarily call for operation.

Book Notices.

This book is distinctly a product of the times. The relationship between injury and disease or disability has become one of the most important questions connected with medicine. In Germany, by the passage of the Unfallversicherungsgesetz, or accident-insurance law, the interests of workmen injured in the pursuit of their occupations are provided for.

This implies careful examination and observation of the injured person and an increased general attention to the traumatic origin of disease. In this country the subject, though less systematically regulated than in Germany, is of great importance. The most trivial injury is often made to serve as the basis of a claim for damages, and court calendars are largely filled with personal-injury suits.

Medical literature reflects these conditions. There are now several periodicals devoted exclusively to the relationship between disease and accident, and the scientific study of the traumatic origin of various diseases, but especially those affecting the nervous system, is more active than ever before.

Monographs, such as Oppenheim’s Traumatic Neuroses, Pearce Bailey’s Accident and Injury, Shuster’s Examination in Traumatic Diseases of the Nervous System, and the one now before us, are constantly appearing.

The aim of the authors has been to provide a handbook for physicians brought in contact with accident cases in which there are lesions or disturbances of the nervous system. They have seen fit to devote the first half of the book, after a general introduction, to anatomical and physiological considerations and to symptoms and methods of examination.

This is an unequal allotment of space, as the subject proper is too long postponed and the book is made much larger than necessary.

The exposition of the relationship between physical and psychical injuries and disorders of the nervous system, in the last half of the book, is concise and accurate.

There is a systematic description of injuries to the central and peripheral nervous system, of the action of accidents as causative agents of neuroses and psychoses and of the influence of traumas in etiology, and of the course of the chronic degenerative diseases.

The work appears an assimilation of facts already known rather than an original contribution. It is, however, a very useful compilation and is to be warmly commended for its thoroughness, its exactness, and for the soundness of the views expressed on unsettled questions.

From an interesting study of cases observed in the Bicêtre over long periods of time the author draws the following justifiable conclusions as to the prognosis of epilepsy: 1. Idiopathic epilepsy is curable in a certain number of cases. 2. The prognosis is better when the convulsions appear at two years of age or later than when they begin during the first year of life. 3. Heredity, either direct or indirect, while it makes the outlook more unfavorable, does not necessarily exclude recovery. 4. Intellectual impairment, moral perversion, anamnesis, etc., make the prognosis worse. 5. Hemiplegic epilepsy is more frequently curable than the idiopathic variety.

In this brochure are considered the clinical and medico-legal relations of imperative concepts and of impulsions to suicide and homicide. The subject is handled in a thoroughly scientific way. The views of alienists prominent in this borderland of medicine and law are given, and many new and interesting cases are added. The author is to be congratulated on his production.

Books, Etc., Received.

Lectures upon the Principles of Surgery. Delivered at the University of Michigan by Charles B. Nancrede, A. M., M. D., LL. D., Emeritus Professor of General and Orthopaedic Surgery, Philadelphia Polyclinic, etc.
With an Appendix containing a Résumé of the Principal Views held concerning Inflammation by William A. Spitzley, A. B., M. D., Senior Assistant in Surgery, University of Michigan. Illustrated. Philadelphia: W. B. Saunders, 1899. Pp. 11 to 398. [Price, $2.50.]

An Atlas of the Bacteria Pathogenic in Man, with Descriptions of their Morphology and Modes of Microscopic Examination. By Samuel G. Shattuck, F. R. C. S., Joint Lecturer on Pathology and Bacteriology, St. Thomas's Medical School, London, etc. With an Introductory Chapter on Bacteriology; its Practical Value to the General Practitioner, by W. Wayne Babcock, M. D., Pathologist to the Kensington Hospital for Consumption, etc. Sixteen Full-page Colored Plates. New York: E. B. Treat & Co., 1899. Pp. 7 to 82. [Price, $1.]

The Panper Inebriate—His Legal Status—Care and Control. By L. D. Mason, of Brooklyn. [Reprinted from the Quarterly Journal of Inebriety.]

Five Hundred and Fifty Surgical Operations without Alcohol. By Charles Gilbert Davis, M. D., of Chicago. [Reprinted from the Western Clinical Recorder.]

An ant Urgent Duty of the Profession. By B. Oettinger, M. D., of Denver. Read before the Colorado State Medical Society.

Cystoid Disease of the Testicle: Teratoma Testis? By F. R. Sturgis, M. D. [Reprinted from the American Medical Quarterly.]

Enteric Fever: its Infection, Pathology, and Present Treatment. By Franklin Staples, M. D., of Winona, Minnesota. [Reprinted from the Journal of the American Medical Association.]

A Contribution to the Study of the Gastric Crises of Tabes. By Seymour Basch, M. D. [Reprinted from the Medical Record.]

Wesen und Behandlung der Verdauungsstörungen Chlorotischer. Von Privatdocent Dr. Albert Albu, Berlin. [Sonderabdruck aus der Zeitschrift für praktische Aerzte.]

Klinisches und Anatomisches zur Lehre vom Magensaftfluss. Von Dr. Albert Albu und Dr. M. Koch, Berlin. [Sonderabdruck aus dem Archiv für pathologische Anatomie und Physiologie und für klinische Medizin.]

**Miscellany.**

An Indian School of Pharmacy.—According to the Pacific Medical Journal for October, a chemical and pharmaceutical laboratory, the first of its kind in India, was opened at Rajkote Kathiawar, Western India, on November 29th of last year. The building, constructed at a cost of Rs. 30,000, is the gift of Azan Wala Laxmon Meram, chief of Thana Deoli. His fellow chiefs have adopted the laboratory as one of their central institutions and have voted Rs. 7,500 for the apparatus and an annual grant of Rs. 8,628 for the maintenance of the institution. The staff of the laboratory, consisting of Mr. H. L. Lee, formerly lecture assistant in the school of the British Pharmaceutical Society, with two native assistants, and a clerk, has already done one term of very satisfactory work with twenty-one students. The object of this laboratory is "to teach the
native medical men or vaidis the proper method of preparing drugs from Indian herbs, to investigate more carefully the properties of those in use, and to discover the virtues of others which, though used locally by herbalists, are not yet known to Western science." Of the twenty-one students, thirteen hold scholarships provided by different States. The remaining eight are private students studying at their own expense.

The Southern Surgical and Gynaecological Association.—The twelfth annual meeting will be held in New Orleans on Tuesday, Wednesday, and Thursday, December 5th, 6th, and 7th, under the presidency of Dr. Joseph Tabor Johnson, of Washington. The programme includes the following titles: Myomatous Tumor of the External Iliac Vein, with a Report of a Case, by Dr. A. M. Cartledge, of Louisville; Nephrectomy, by Dr. Howard Kelly, of Baltimore; Ureterectomy, by Dr. J. Wesley Bovoe, of Washington; Renal Calculus, by Dr. Richard Douglass, of Nashville; Serious Complications following the Passage of the Urethral Sound, by Dr. W. E. Parker, of New Orleans; Gunshot Wounds of the Abdomen, by Dr. H. H. Grant, of Louisville; The History of Pulmonary Insufflation and Artificial Respiration in Infrarhachic Surgery by Intubation of the Larynx, by Dr. R. Matas, of New Orleans; The: Tech

How a Doctor may be Called from a Theatre.—A newspaper statement lately appeared to the effect that the Jersey City theatres were to provide bulletin boards in the lobby upon which a physician could write his name and the number of his seat, so as to make it easy to call him out in case of need without disturbing the rest of the audience.

Obstetrics and Nature.—Dr. B. F. Chambers (Medical Monitor; Gailard's Medical Journal, October) says that a physician whose practice rarely causes him to venture beyond the suburbs of a city has lived but half of his life, and some of the experiences of the practitioners located where the owls hoot loud and long would sound like a narrative taken from a "yellow-back" novel.

Dr. Chambers was called to attend Mrs. S., aged thirty-four years, while in labor with her fourth child. He found the patient on her knees by the bedside, with her head resting on the bed rail (this being a common position in that locality, through the teaching of a midwife). On observing the frequency and quality of the pains, he invited the patient to lie down for her comfort and his convenience, but was informed that she had had more babies than he and knew full well which was the easier position.

After examination and a few minutes of mental philosophy in making allowance for the peculiar position of the patient, he found the fetus in the second position. Soon after his examination he noticed the patient herself making an examination, and she informed him in due time that it was not right; that (to use her own language) the big part of the head was not as it had been with the other children. Finally, to add to his astonishment, she arose, stooped forward, and caught something between her limbs, which he could not see for her gown, but presently he heard the cry of a much-abused urchin, which was the signal for scissors and band. He ligated the cord, turned to place the child in the attendant's care, and behold! the patient had the umbilical cord in her hand and was pulling the placenta from her body. Dr. Chambers was a victim of astonishment, fright, and anger. He got to...
Dr. Fraenkel said that the chief question to decide was whether there was any pathological relation between the Strümpell-Jadassohn type and cases of chronic rheumatoid arthritis deformans. Of course, chronic rheumatism would give rise to a stiff back, but there would not be the clinical symptoms emphasized in the paper just presented.

Dr. Gibney said that his attention had been called to the subject about eighteen years before by a case of spondylitis deformans, and since then he had been trying to distinguish the many varieties of stiff back that came under his observation. He had seen a number of cases of senile arthritis.

Dr. C. L. Dana said that he had been taught that there were two types of arthritis deformans—viz., the type beginning in the small joints and progressing steadily, and the senile type, beginning in the back and hips and stiffening them. There were almost always some cases of that kind in Bellevue Hospital. He had studied his own cases in connection with those reported by others, and had come to the conclusion that the cases of the Strümpell-Marie type were nothing more than arthritis deformans. He felt sure that, in due time, cases would be found in which the spine only was affected and only the root joints. He now had a case in which only the hips were affected, the spine not having been involved as yet. He did not personally feel that either Strümpell or Marie had added anything at all to our clinical knowledge of these cases. Twenty-five years ago it had been stated very clearly that rheumatoid arthritis sometimes presented this particular form. Von Bechtereff had certainly described types that were distinctly secondary; the case reported with autotomy seemed to him one of specific meningitis. There was a type of stiff spine which had been described by Dr. Bradford, of Boston, and proved by him to be due to gonorrhoeal rheumatism. In this case the history was most conclusive. He now had under observation a very bold kyphotic spine, and there seemed to him but little doubt that the case was rheumatoid arthritis. He therefore believed that spondylole rhizomélique was a nosological superlunary.

Dr. George R. Elliott said that three years before he had examined under ether, with Dr. Fraenkel, one of the patients presented that evening, and had found that the rigidity had remained. Since that time the case had proved to be a classical one of spondylole rhizomélique of the Marie-Strümpell type. He was not yet willing to admit that we were dealing with a disease per se. That it was not arthritis deformans admitted of little doubt. It had been said that this type could be distinguished from arthritis deformans by the fact that the latter affected chiefly the small joints, but he believed such a statement must be modified. A clinical examination of so-called arthritis deformans revealed two distinct findings—viz.: one, an atrophic process, in which, after acute or subacute symptoms, the joint got smaller, and a second clinical picture, in which the joints became hypertrophié. Pathological study supported the clinical findings. He could see nothing in either the clinical history or the pathological study of the type presented which differed from the hypertrophic form of the smaller joints. He was of the opinion that there were two distinct diseases—arthritis deformans and a proliferating arthritis. This might be called the Strümpell-Marie type or, better, central type of the proliferating kind, as distinguished from the peripheral type of the proliferating kind; but it was not to be con-
founded with arthritis deformans proper. That the small joints always escaped, as had at first been held, was not true. Marie himself had reported affection of the small joints in 10 per cent of his cases. This statement was supported by Bannatine, of England, and Goldthwait, of Boston. There was much about the type of disease under discussion to suggest a degeneration—viz., gradual destruction of soft parts of joint and partial replacement by osseous material, the parts becoming welded together with very little excess of tissue or deformity. The proliferation, which was slight, appeared as a secondary process, the result of irritation. It was very unlikely that producing so-called arthritis deformans proper. It was not so rare as might be supposed from the few cases so far reported. Dr. Goldthwait had reported, at the last meeting of the American Orthopedic Association, ten cases which had come under his observation. So marked a type as one of the cases just presented was rare indeed; it was a classical example of the Strümpell-Marie type or central type.

Dr. W. R. Townsend said that he had at present under his care a child presenting a picture very closely resembling arthritis deformans. If he remembered correctly, Charcot had insisted that these cases were not rheumatic, but neurotic. He had seen a number of cases of rigid spine, and had supposed them to be either rheumatic or of the types of arthritis deformans of the neurotic character described by Charcot.

Dr. Collins said that a discussion of this kind could not be profitably carried on until the various conditions spoken of had been clearly distinguished. He then reported two cases occurring in women.

The speaker said that cervical meningitis would produce a stiff back and a stiff neck—a symptomatic stiff back—and it seemed to him that this was the character of von Bechtereff’s case.

The president, Dr. Peterson, said that he had seen three or four cases, all of which he had diagnosed as arthritis deformans of rheumatic origin.

Dr. Saels remarked that the von Bechtereff type had been brought into the discussion because it had been necessary to distinguish it from the others, and for this reason he had endeavored in the paper to show more clearly than previous writers that von Bechtereff’s case was of the secondary type. The morbid changes were quite different in the two types. In the European journals there had been much opposition to the view that they were at all closely allied to rheumatism or to arthritis deformans.

Blindness due to Intestinal Haemorrhage.—At a meeting of the Section in Ophthalmology of the College of Physicians of Philadelphia held on October 2d Dr. William M. Sweet showed a patient in whom blindness had occurred six days after profuse haemorrhage from the bowels, the vision of the left eye being entirely lost, while in the right eye a small area to the temporal side of the fixing point was preserved. Ophthalmoscopic examination made three days after the haemorrhage showed moderate contraction of the retinal arteries, paleness of the optic discs, with the margins slightly hazy, and slight oedema of the retina, especially toward the foveal region, but no retinal haemorrhages. From the lower border of the right optic disc a ciliary artery passed toward the fovea, and the preservation of some vision in this eye was probably due to the blood supply from this source.

Of the theories advanced to account for cases of blindness after haemorrhage, that of Westhoff and Ziegler, who believed that the ischaemia produced a fatty degeneration of the nerve fibres, would seem to explain the symptoms in many of the cases. Theobald considered that the degeneration followed a thrombosis in each central artery of the retina, the enfeebled blood current in the retinal artery being further obstructed by the intraocular tension. In this case, however, there was not the marked contraction of the retinal arteries that might be expected to follow a plugging of the main arterial supply of the retina. Ziegler’s autopsy, twenty days after the haemorrhage which led to the loss of vision, showed fatty degeneration of the optic nerves and their intraocular expansions, a condition which Ward Holden had shown, by experimental researches, to follow degenerative changes of the retinal ganglion cells.

Dr. de Schweinitz referred to the work of Ward Holden in investigating pathological changes in this and analogous cases. He believed that the blindness was due to oedema of the retina followed by early changes in the ganglion cells. These changes led to degeneration of the cells and fibres extending upward into the optic nerve as far as the chiasm. The symptoms in Dr. Sweet’s case seemed to be well explained by this theory.

Bacilli as Lethal Weapons to Extort Blackmail.—The Indian Medical Record for September 27th says that, according to a Vienna correspondent, a black-mailing case with a humorous aspect has been occupying the attention of the criminal courts at Grazt. An elderly lady of great wealth one day received a letter saying that if she did not send the sum of ten thousand florins in small bank notes to a given address the writer would work a fearful revenge by opening in her room a bottle containing the bacilli of various infectious diseases, which would certainly cause her death. The lady appealed to the police, who discovered the would-be blackmailer. A bottle found in his possession really contained bacilli, which the culprit, who was a medical student, had stolen from his professor’s lecture room. A sentence of eighteen months’ hard labor will doubtless prevent this promising youth from further blackmailing enterprises.

The Hospital Ships for South Africa.—The London correspondent of the Medical News in its issue for November 4th says two Union Cape liners, Spartan and Trojan, have been chartered for hospital ships, and one of them has already been turned into an admirable floating hospital equipped with the latest electric fans for ventilation, sixty-five swing cots so arranged that they can swing with the motion of the vessel or be locked absolutely steady, sisters’ quarters, and medical officers’ quarters. A most important part of the equipment, of the need of which in tropical warfare our terrible experience before Santiago served as a magnificent object lesson to the civilized world, is a huge carbon-dioxide refrigerating machine capable of turning out half a ton of ice a day. The operating room is placed in a super-structure on the upper deck and is beautifully fitted up with the latest mechanism in operating tables. A complete Röntgen-ray apparatus for the localization of bullets finishes this almost ideal equipment. As the heaviest part of the fighting is expected to occur from within sixty to a hundred miles of the coast, a floating hospital of this description in the sea air will be a perfect godsend to many a poor fellow in the stream of wounded pouring back from the front.

NOTES UPON
X RAYS AND INJURIES OF THE HEAD.

BY J. RUDIS-JICINSKY, A. M., M. D.,
CEDAR RAPIDS, IOWA.

Something over three years ago, having an unusual number of cases of tuberculosis in a part of the country comparatively healthy, I made a few experiments with X rays and their efficiency in medical diagnosis. I was particularly anxious to make good radiographs of different parts of the lungs. Diseased portions showed up well in marked contrast to the clear space of the normal lungs.* Knowing this, and from other experiments, I had collected many proofs that it is only a question of time when the X rays will and must assist us in the field of medical pathology, as well as in surgery. I went to work to study the means of diagnosis in cases of injury of the head, and tried my best in experimenting to illustrate, with comparatively very short exposures, the increasing efficiency of the Rontgen light in this line also. I know that this plan of diagnosis has been tried, but in a great majority of cases it has not been a success, and that by most surgeons it is considered unsafe. Notwithstanding all this, I could not banish from my mind the conviction that if proper care and some modifications were used, it could not result in any injury to the patient, and might help us along very well to make an early and proper diagnosis. To be conservative and from seeing the radio-

Fig. 1.—Normal frontal and both parietal sutures.

graphs made,* we have to acknowledge that the use of the X ray is very promising in this regard.

We know that in examinations of head injuries the main feature is the estimation of the intracranial lesion.† With the help of the X ray the local cranial wound may be much better examined than in the usual

Fig. 2.—Brain exposed: four shots (lead) behind the bones.

way. If fracture exists, whether it is simple, compound, or complicated, with fissuration or depression, is determined in five to ten seconds, without any danger of complications, inflammation, etc., because the trephine or elevator may be applied at once to arrest bleeding and remove pressure of the bone. You may see also the simple or stellate fissure of the inner table in plain, dark lines, without prolonged and sometimes dangerous exploration, and when hematoma is present it cannot mask the bony outlines. The shadow of bone and the shadow of hematoma are altogether different, and you can determine on the plan of treatment in such cases much better, especially if the attending symptoms are taken into consideration. In cases of foreign bodies the results of diagnosis are still better obtained (compare the radiograph Fig. 1 of the normal skull with Fig. 2, brain exposed for experiment on cadaver). There is a marked difference in shadow between the bony parts and the four shots (lead) introduced behind the bone. We may see and observe not only how large the shots are, but how deep they went, and measure this according to the intensity of the shadows. The same radiograph and Fig. 5 show the orbit very well and plainly, proving that we may search for foreign bodies in the eye with the X ray just as well.‡ In cases of hematomata the picture of the same may show beautifully, as in our case, Fig. 3. In cases of bony growths within the cranial walls, some tumors of the brain between the cranial wall and

* Some of the negatives from which our illustrations are taken are full of detail which is lost entirely in print.
† Allison. Western Surgical Society, December 29, 1898.
I would not advocate giving up any of our other methods of making a diagnosis, but would strongly urge making a careful X-ray examination of the head in case of injury, and think that with the old but good rules of Broca, Séguin, Mills, Nancrède, and others for cerebral localization, the application of the X ray will be considered appropriate* (Fig. 5) to confirm our diagnosis early and make it sure—surgically speaking—in our care of these cases. One may see the sutures of the skull plainly and can make out the grooves for the meningeal arteries so well, that the search for the fissure of Rolando must be a much easier task and a simpler one.

The following case will illustrate the usefulness of the X ray. The symptoms were obscure and pointed to a non-operative line of treatment, but the X ray proved that we had to operate. In reporting the case I fully realize that one or two cases are very little to build on, but let us see:

Joseph F. B., aged thirty-nine years; sunstroke six years ago. Since that time had complained of dull, persistent headache on the left side of the head, changed disposition, was irritable, had vertigo, dyspepsia, vomiting; soon followed by slight palsy, but no convulsions. Lately, retention of urine and symptoms more obscure. The tone of the muscles and intellect were unimpaired. With the parts of the head not examined covered with stanniol and those exposed oiled—for protection against burning—the X ray revealed under the parietal bone at the sagittal suture on the left a large epidural clot† (Fig. 3). The clot, amounting to four ounces, was removed, and recovery followed in three weeks, without any complication.

The pictures are the results of my own actual and personal experimentation, proving satisfactorily that the shadows which are seen most beautifully correspond exactly with the radiation from the disk of platinum in

† Spark used, twelve inches; distance of the tube from the object, ten inches; plate right behind, duration of exposure, five seconds; angle at which the picture was taken, 36°; plate of tungstate of calcium over the dry plate to shorten the exposure.

4. With the help of the X ray we may know how far to go, and relieve the intracranial pressure perhaps by paracentesis capitis, and in non-congenital cases give much benefit.*

* The proportion of recoveries being about one in four, and at least ten cures having, according to Thoen, been effected by such procedure.
the Crookes tube. Having this in mind, we must always know the power of our X ray, the distance of the tube from the object, the distance from the plate, the duration of exposure, and the angle at which the picture is taken. If we wish to make a correct diagnosis and produce an accurate picture, we must never be satisfied with one radiograph of the case, but make it also our duty to compare the picture of the injured part with the normal one. Work as rapidly as possible, make short exposures, and protect your patient. To read correctly the lesson of an X-ray picture, know your anatomy and pathology, keep the obliqueness of X rays always in mind, make it as nearly life size as possible, to get sharply defined outlines, remembering that we are dealing with shadows only, and use a proper dividing screen (Dennison’s, etc.) for measurements and exactness of your pictures.†

There is no question that we stand upon the vantage ground of more accurate observation with the application of the X ray, and may hope that the results of these and other experiments, in which the most exact science will be followed with the honest intent “pro bono medicina,” will be such that an endeavor will be made to extend the usefulness of the X ray in all our work “to relieve suffering and prolong life.”

VACCINATION.

By F. G. ATTWOOD, M.D.,
WASHINGTON, D. C.

It having fallen to my experience recently to observe a number of hideously sore arms caused by vaccination, I have been led to inquire whether such were the evidences of true vaccinia or of some extraneous infection.

After a series of interesting experiments I have reached the conclusion that most of the untoward results of vaccination are due to the employment of an improperly prepared, and more especially an improperly protected virus. Would any sane physician, with the least knowledge of or experience with infection processes, be willing to make an abrasion in the cuticle of an innocent person and then proceed to rub upon the denuded surface any other animal substance, such as blood serum, which had previously been exposed to the atmosphere for weeks? Yet, bold as the statement may seem, that is precisely what is being done every day, under the name of vaccination, in the use of the unprotected points. In the eyes of careless or thoughtless persons ivory points seem harmless, indeed safe, because they have a white, clean appearance. But the educated physician, familiar as he is with the dangerous and insidious action of micro-organisms, is not so easily deceived. He knows that on a vaccine point there is an excellent culture medium which has been exposed to infectious contamination. Then, after a sufficient time has elapsed for germ life to develop, the infected matter is introduced into the blood of some healthy human being, with no thought or concern as to what organisms may find entrance there. Need it surprise us that antivaccinationists are active and on the alert? Can we assure the victim of such treatment that he has been successfully vaccinated, and is therefore protected against the infection of variola, after he has been confined to his bed for days, and has suffered more or less for weeks?

True, his arm has been sore, fearfully sore, but is that vaccination?

Antivaccinationists, from the time of the immortal Jenner to the present day, have pointed to such cases as these in justification of their teachings. The photographs, which are here produced, are cases which I have observed. They are not presented on the grounds of novelty, for every medical man has seen the same condition, but rather to illustrate emphatically what I have stated.

The question naturally arises, What practical method, if any, has been devised to obviate such deplorable results? My answer to this question is, Use sterile glycerinated lymph, hermetically sealed in glass tubes, and thus protected from accidental contamination. As evidence of the high esteem in which glycerinated lymph is held I append this letter, received from Professor Welch, of Johns Hopkins University, whose word is authority in medical teaching:

‘Baltimore, March 12, 1899.

Dear Dr. Attwood: I have received your letter and the photograph. It is unquestionable that the glycerinated vaccine lymph is the best, and it ought to replace the ivory points. The gelatin destroys most contaminating bacteria to which such results as that shown in the photograph are due, and leaves unaffected the organism of vaccinia. Thus very sore arms from extraneous infection are almost excluded by the use of the

glycerinated virus. Parke, Davis, & Co.'s aseptic vaccine (glycerinated) is trustworthy and as good as any to be obtained.

"Very truly yours,

WILLIAM H. WELCH."

Glycerinated vaccine is aseptic vaccine. It consists of the pulp of the cowpox vesicles mixed with pure glycerin. The glycerin destroys the comparatively few streptococci or other bacteria likely to be present despite the most careful manipulation. While glycerin is not a powerful germicide, it is sufficiently so, as has been demonstrated, to render germ free and to preserve aseptic the virus with which it may be mixed.

To those who are acquainted with the methods of Messrs. Parke, Davis, & Co. in the production of serums it will be unnecessary for me to state that in the elaboration of vaccine they guard every step with the most uncompromising scrutiny. They assure the purity of their product by the most rigid antiseptic and aseptic measures. The heifers, before being vaccinated, are tested with tuberculin. As an additional safeguard they are slaughtered afterward and a careful inspection of the carcass is made by an expert. If any evidence of disease should be found the vaccine virus from that animal is entirely destroyed.

In performing a vaccination the part selected should be made surgically clean. The site is then scraped with a sterile lancet until serum begins to exude. If by too vigorous scraping blood should be drawn, the spot should be carefully dried with a pledget of sterile cotton before applying the lymph. The ends of the capillary glass tube are then broken off, and the lymph is ejected upon the site of scarification by means of the rubber bulb placed upon one end of the tube. The lymph is then thoroughly rubbed into the abraded area with the lancet and the spot is permitted to dry. Protection is afforded by covering the spot with a pad of sterile gauze, retained by means of a bandage.

In conclusion, it may not be inappropriate to call attention to several sources of infection, to guard against which as much care should be exercised as in undertaking any operation involving an incision into the sound integument: these are dirty scissors, unwashed arms, unwashed hands, and unclean underwear, which should never be allowed to come in contact with the site of vaccination. The method which I use to make the selected spot surgically clean is about as follows: The arm is first washed well with soap and water and dried; then the point of inoculation is bathed with alcohol on a pledget of cotton, and after the alcohol has evaporated the scarification is made.

Another method which I have tried with good results is to subcutaneously inject the glycerinated lymph with a hypodermic or an antitoxine syringe. The syringe must be so constructed as to admit of thorough sterilization before use.

FURTHER EXPERIMENTAL RESEARCHES ON THE EFFECTS OF DIFFERENT ANÆSTHETICS ON THE KIDNEYS.

By ROBERT COLEMAN KEMP, M.D.

(Concluded from page 772.)

Effects of Ethyl-Chloride Anæsthesia.—That the effect of ethyl chloride is chiefly respiratory we learn from the following experiment: Mr. Moschowitz, a chemist of this city, anæsthetized for me a cat with chloroform. The anæsthesia was normal. On changing the anæsthesia to ethyl chloride, stertorous breathing, difficulty with respiration, leg tremors and convulsive movements of the hind legs, and temporary tonic spasm of the hind legs resulted. These symptoms corresponded to the respiratory effects of anæsthol.

Conclusions.—As regards ether, it would appear that this agent produces a special contraction of the renal arterioles, with a consequent damaging effect upon the renal secretory cells, similar to those which follow clamping the renal artery. The kidney shrinks in bulk, with consequent fall of the onometric tracing, and accompanied by diminution of secretion, marked albuminuria, and, finally, suppression. As remarked before, this condition of the kidney is not due to any change in the general arterial circulation, since it occurs not only when pure ether is administered, but also in the mixtures in which it is a constituent, if the semi-closed or closed method is employed. Thus an ether kidney but a chloroform heart ensues, as in the use of the A. C. E. mixture. When changed to the open method of anaesthesia, the ether-kidney trace disappears and is replaced by that of chloroform.

These facts would seem to contraindicate the use of ether as an anaesthetic when renal disease is present, and particularly when with the albuminuria there is a tendency to pulmonary oedema.
The effect of chloroform upon the kidney seems to be nil. The oncometric curves are nearly normal, and are affected only through sharing in general circulatory changes. The secretion of urine continues up to the last moment of life, and the albuminuria is so slight that its presence at all is apparently due only to respiratory interference. Meantime the action of chloroform on the heart, as shown by the carotid tracings, is directly depressing. Ether, on the other hand, shows evidence of cardiac stimulation throughout.

The A. C. E. mixture shows the special effects both of ether on the kidneys and of chloroform on the heart, either being predominant according to the mode of the administration. If a large percentage of air is simultaneously inhaled, as is the case when chloroform alone is administered, the effect is that of chloroform—cardiac depression without effect of ether upon the kidney. If, however, the A. C. E. mixture is administered more as ether is when used alone, then a study of the carotid and kidney tracings shows clearly that we have both the cardiac depression of chloroform and the renal derangement of ether combined. This seemed to cause such powerful effects upon the breathing and upon the heart that artificial respiration had to be resorted to in every dog to which this mixture was freely administered, which was not the case with either ether or chloroform.

So far as our observations go, therefore, we fail to see any advantage in this mixture of chloroform and ether, but rather the reverse.

These objections appear to be still more applicable to Schleich's anaesthetic. The cardiac depression of chloroform and the renal disturbance of ether are simultaneously developed in the tracings, similar to but to a greater degree than with the A. C. E. mixture. Schleich claims that mixtures of different anaesthetics of different boiling—i.e., maximum evaporation—points are safer than the administration of the anaesthetics alone, on the assumption that the absorption of an anaesthetic as to quantity depends upon its boiling point. The more volatile an anaesthetic is, the less will be absorbed into the blood in a given time. Hence ether, whose boiling point is 33° F., will not be absorbed so rapidly as chloroform, whose boiling point is 143° F. If, therefore, an anaesthetic could be produced whose boiling point was the same as the normal temperature of the blood, the exact amount absorbed with each inspiration would be eliminated by each expiration. By causing the mixture to be at different degrees above this point, he claims that we can regulate at will the excess which the expiration would not remove, and thus the amount of the anaesthetic retained in the blood. His addition of petroleum ether or benzene to sulphuric ether and chloroform was further to facilitate the formation of a mixture or solution of anaesthetics which would afford a safer means of absorption.

We believe that practically this reasoning is fallacious, because it assumes that these mixtures or solutions constitute a new chemical homogeneous compound which will always be inhaled as one substance in definite chemical proportions, just as a compound salt is one substance when swallowed after solution in water; whereas, the fact is that ether remains ether and chloroform stays chloroform during the inhalation, and that the proportion of either which will be absorbed will depend upon the mode of administration, a tight cone allowing an amount of chloroform to be taken which would be extremely dangerous, while the free admixture with air would so lessen the absorption of ether that its specific effects would be proportionately lessened. Meantime the adoption of benzine is not the adoption of an anaesthetic, for Dr. S. T. Meltzer, in a communication to us on his experiments upon rabbits with petroleum ether, by inhalation through mouth and nose, as well as through a tracheal cannula, says: "Petroleum ether is not a narcotic. If a rabbit was put under deep anaesthesia by ether, and then ether suspended and petroleum ether administered, the lid reflex soon reappeared and the rabbit woke up. The inhalation of pure petroleum ether alone soon brings out a distinct tetanus and opisthotonos, to which the animal soon succumbs if the inhalation be continued. If the inhalation be discontinued at the appearance of the convulsions, the animal survives the tetanus, but this is then followed by a distinct paresis of all the extremities. If ether is given with the petroleum ether, the tetanus movements are suspended, but not so the paralytic after-effects; the rabbit dies of paralysis of the respiratory muscles."

There is, moreover, a physical reason for doubting the manageability of mixed anaesthetics due to the fact that if two agents of different maximum points of evaporation are mixed together, the more volatile of them will increase the evaporation of the other by carrying off more of the less volatile one than if the latter were vaporized by itself. Thus more chloroform would be inhaled if mixed with ether than if it were administered separately.

In addition, in curarized animals this fact was demonstrated physiologically, for when respiration was in abeyance an immediate chloroform effect on the circulation was produced if Schleich or A. C. E. were employed as an anaesthetic, when these solutions were held above the level of the animal; whereas, with pure chloroform by the same method a considerable interval elapsed before the chloroform effect was produced on the heart.

The ether in the mixtures was thus a vehicle for the chloroform.

That Schleich's mixtures have been used in a number of cases without dangerous effects is no evidence that they are safe, for the same may be said of chloroform and of ether the world over. Mixed anaesthetics of any kind might be employed in hundreds of instances without unpleasant results, though actually they were more dangerous than unmixed agents, for with chloroform
The following would seem to be the most scientific method to observe the actual changes that occur under each anesthetic:

1. Examine urine carefully, and measure same for twenty-four to forty-eight hours before operation; the urea, indican, and chlorides should be noted.

2. Catheterize the patient immediately before the anesthetic is started. This eliminates residual urine from any cause whatever. I believe the nervous element may prevent the complete voiding of the urine. Examine this specimen.

3. Catheterize the patient immediately at the close of the anesthesia, noting time and nature of operation, quantity of anesthetic, nature and method of administration, and how borne by patient; measure the urine, and you have the absolute results of the anesthesia.

Test urine for specific gravity and quantity secreted, also for albumin, sugar, and casts, etc., and also for indican, chlorides, urea, etc. Specific gravity and quantity have been noted at Johns Hopkins.

The following interesting fact I have noted: Indican was increased very markedly by ether, and also was produced markedly if absent before anesthesia; and if present in a small quantity, this was considerably increased. The same result was produced by chloroform, but was less in quantity than with ether. With nitrous oxide indican was produced or increased, but also less than with ether.

I was able to make these tests on twelve cases of ether narcosis, three of chloroform, and two of nitrous oxide and oxygen.

The comparative effect between chloroform and nitrous oxide was difficult to judge of, on account of the few cases, though the nitrous oxide seemed to produce a trifle less than the chloroform. As regards albumin following the method by catheterism, as above described, in twelve cases of ether I found a trace of albumin in three cases where there was none previous to operation, and in one case a slight increase where it previously existed; no renal complications, however, followed, so far as I could learn. With chloroform, three cases, I found no change. In two cases of nitrous oxide no change in urine after operation, in one case there being no albumin previous to it.

In the other case of nitrous oxide and oxygen there was a trace of albumin before operation and a few casts. After operation the albumin disappeared, the number of casts diminished, and the patient passed seventy-five ounces of urine in the first twenty-four hours after operation, against fifty-two ounces twenty-four hours before.

There was a special reason for this—namely, on account of the slight changes in urine. A hypodermoclysis of blood pressure and the consequent effect on the heart could readily account for the fatal result. Dr. Bennett is accustomed to administer ether first for a short period between the nitrous oxide and the chloroform. The circulatory changes then occur gradually.

---

* In the report of Roosevelt Hospital for the year 1898, on the surgical division the percentage of deaths from renal complications traced directly to the anesthesia was 4.4 per cent., in the gynaecological division 9 per cent., and a total percentage in the combined services of 5.5 per cent. These are tabulated in the appendix. Temporary albuminuria, 65.8 per cent. due to ether.

† The immediate substitution of chloroform for nitrous oxide is a dangerous procedure, since nitrous oxide causes extreme vascular contraction and chloroform dilatation of the vessels. A sudden alteration...
sis of normal saline solution, six ounces, was given just before the anesthetic was removed. This procedure in such conditions seems of value, as the result is simple but efficacious. An enema is apt to be voided or objected to by the patient. A convenient region is the lumbar, between the crest of the ilium (posteriorly) and lower border of the ribs, gentle massage being employed.

The patient had no renal complications. This method is to be employed when the question of renal (subsequent) complications might occur.

As Dawbarn does with "infusion to prevent shock," so should we with "hypodermoclysis" to minimize in so far as possible the danger of renal complications due to the anesthetic in those cases where disease of the kidneys already exists or is suspected. This rule should be applied to any anesthetic. The employment of that anesthetic least deleterious to the kidneys with the addition of hypodermoclysis at the close of the operation would seem a logical course to pursue.

The question as regards the possible significance of indican as being produced or increased by anesthetic would seem worthy of further investigation; also as to whether it has any bearing on the gastro-intestinal derangements subsequent to anesthesia, or to the disturbance of the renal functions, or is of no significance whatsoever. Unfortunately, I was able to investigate a few cases only, and in the human subject. It would be well to test many cases clinically with the different anesthetics, and also to carry on further physiological experiments with animals. That indican, like albumin, was produced most markedly by ether, and so on again, like albumin, on the descending scale, with chloroform and nitrous oxide, would seem somewhat significant. Possibly it may be due merely to the general interference with the intestinal functions, the digestive secretions included; and in regard to this question I should be especially pleased to hear the opinion of Dr. Meltzer. Unquestionably, investigation of a thorough character would be of scientific interest.

Having abused your patience and appropriated a considerable period of your valuable time, I shall bring this paper to a final close, and while doing so I wish to assure you that my remarks on surgeons and their relations to anesthesia were of a most general character; for, happily, within the last two years the skilled anesthetist is becoming a prominent factor, and instruction is being given in anesthesia in some of our best hospitals to the hospital interne. This is as it should be, and I have merely wished to emphasize, by "comparison of the old methods with the new," the desirability that the medical profession at large should bestir itself. The "sins of omission and commission" that I have described I have myself been guilty of, I must freely acknowledge, and I believe that you will all agree with me that through "errors," and, mark you! the "honest confession" of the same, and the endeavor thereafter to avoid them, we reach at last, "the truth," which is our goal.

**Appendix.**

(A) Deaths from renal complications traceable directly to the anesthetic (ether). Prepared by Dr. Creevey, house surgeon, from the table of deaths (surgical division, and also gynaecological division) in the Hospital Report of Roosevelt Hospital, 1898.

(B) Table prepared by Dr. Creevey, house surgeon, showing the percentage of cases, operated with ether as the anesthetic, in which albuminuria was produced. This covers a period of about two months at Roosevelt Hospital, full of 1898. By courtesy of Dr. Charles M. Burney, attending surgeon.

Deaths due to Renal Complications caused by the Anesthetic—Ether. (From the Report of Roosevelt Hospital for the Year 1898—Table of Deaths following Operation.)—Total deaths of patients operated on in surgical division, 68. The anesthetic (ether) the cause of the exacerbation of renal symptoms resulting death. Diagnosis: Acute appendicitis; suppressed urine.

This case reported by the house surgeon as follows, being abstracted from the history of patient filed in the records as acute appendicitis; suppression of urine.

Case I.—Mary C. T., aged fifty years.
Diagnosis: Acute appendicitis; suppression of urine.

Urinary analysis, December 5, 1898 (before etherization): Amber; acid; very faint trace of albumin; no sugar; specific gravity, 1.026; epithelial cells, pus, and granular casts.

Operation. December 5, 1898.—Cystotomy and drainage; ether employed.

Urinary analysis, December 6, 1898 (first specimen after etherization): Amber; acid; trace of albumin; no sugar; specific gravity, too little urine to secure it. Epithelial cells, mucus, triple phosphates. Died forty-two hours after operation, having excreted in all this time only eight ounces of urine, although infused twice, each time a thousand cubic centimetres of normal saline solution. To the anesthetic as a chief factor the exacerbation of renal symptoms and consequent death were imputed, and justly so.

See page 107 of Hospital Report, 1898. Hernia, inguinal, strangulated; intestinal paresis; suppression of urine.

Case II.—A. H., aged twenty years (ether the anesthetic). Urinary analysis, March 6, 1898 (before operation): Yellow; acid; no albumin; no sugar, specific gravity, 1.024. Microscope negative. Urine normal.

Operation.—Herniotomy and drainage, March 6, 1898.

Urinary analysis, March 7, 1898: Yellow; acid; ten per cent. albumin; no sugar; specific gravity, 1.016. Microscope: Hyaline and granular casts. Died in forty-eight hours, intestinal paresis and suppression of urine following operation.

Case III.—Edward Me. D., aged thirty-four years, page 107. Diagnosis: Perinephritic abscess; uremia. Urinary analysis, November 19, 1898 (before operation): Yellow; acid; no albumin; no sugar; specific gravity, 1.031. Microscopic: Urates.

Operation: Lumbar incision and drainage, Novem-
KEMP: EFFECTS OF ANÆSTHETICS ON THE KIDNEYS.

November 19, 1898. Urinary analysis, November 21, 1898: Amber; acid; faint trace of albumin; no sugar; specific gravity, 1.019; hyaline casts. Died on ninth day of uraemia.

On the surgical division, therefore, of sixty-eight deaths following operation, three deaths have been traced to the anaesthetic (ether) as the cause, and that, too, by its deleterious action on the kidneys.

In Case I there were evidences of slight renal trouble before operation in the specimens examined on the day of operation. Immediately after the operation the albumin increased slightly, but the most significant feature is the fact that the first urine passed after operation was so small in quantity that sufficient could not be secured to obtain the specific gravity, and this condition rapidly went on to acute suppression, so that in forty-two hours the patient died from the suppression, only eight ounces of urine being secreted in this period of time, in spite of two infusions having been given. It seems impossible for a "physician of average intelligence" to impute this result to anything but the effect of the anaesthetic, as causing an exacerbation of previous renal trouble, especially as the operator was a skillful surgeon and all due precautions were taken. Any other possible view would be a slight to his recognized ability.

In Case II (ether operation) the urinary analysis was "normal" before operation (the same day). An operation for "strangulated hernia" was performed. Urinary analysis the day following showed (by volume) ten per cent. of albumin and hyaline and granular casts.

In forty-eight hours after operation the patient died of suppression of urine and intestinal paresis. This case again can not be questioned.

In Case III the urinary analysis was "normal" before operation (the same day), though the patient suffered from "perinephritic abscess." The element of pus, one of the "loopholes" by which some surgeons endeavor to escape placing the responsibility on the anaesthetic, here existed; but, unfortunately for these gentlemen, the kidneys were evidently as yet in good condition; and, furthermore, the free lumbar incision and drainage, which were performed the same day of the urinary analysis, would, they must admit, diminish the chance of infection to the kidneys, on account of the ready exit afforded to the pus. Nevertheless, albumin appeared after operation. On the second day a faint trace of albumin and hyaline casts were found, and the patient steadily became worse, and died on the ninth day of uraemia. The house surgeon (Dr. Creevey) informs me that the drainage, etc., was perfect, and the cause of death was unquestionably uraemia as a result of the anaesthetic.

Note.—There were several other cases in which the house surgeon imputed to the anaesthetic the subsequent renal difficulty, and believed it to be a factor in the death of the patient. These cases were thrown out of our record as doubtful. However, three cases of death out of sixty-eight fatal cases gives 4.4 per cent. of deaths, in which the anaesthetic (ether) is a factor, or accessory factor, due to its effect on the kidneys.

Gynaecological Division.—Of deaths following operation, twenty-two are reported. Of these there are two deaths imputed to renal complications due to the anaesthetic (ether) as a factor or an accessory factor.

These cases were tabulated for me by Dr. Creevey (house surgeon).

Case I.—Franciska G., aged forty-eight years.

Diagnosis.—Fibromycoma uteri; chronic nephritis; suppression of urine. Urinary analysis, July 5, 1898 (before operation): Acid; specific gravity, 1.007; albumin, trace; no sugar. Microscope: Pus and hyaline casts.

Operation.—Complete hysterectomy, July 6, 1898 (ether). Urinary analysis, July 9, 1898: Acid; specific gravity, 1.010; albumin, five per cent. by volume; no sugar; hyaline casts. Patient steadily became worse. July 16th.—Only two ounces of urine passed in twenty-four hours. Died. 17th.

Evidently an acute exacerbation of a chronic nephritis, and only to be traced by the history to the anaesthetic.

Note.—The following case is of special significance, as it demonstrates that a complete diagnosis and the chief factor of death are not always written down in the history heading.

Case II.—Theresa S.

Diagnosis.—Fibromycoma uteri; broncho-pneumonia. Urinary analysis, July 12, 1898 (before ether): Acid; specific gravity, 1.030; no albumin; no sugar. Microscope: Calcium oxalate.

Operation.—On the same day, July 12, 1898, complete hysterectomy. Urinary analysis, July 14, 1898: Acid; specific gravity, 1.024; albumin, five per cent. by volume; no sugar. Microscope: Granular casts; red cells. Died on the third day after operation.

Broncho-pneumonia was noted in the diagnosis, but the severe renal complication was not. This was doubtless through inadvertence. Yet certainly the histories should be carefully searched to secure accurate results, when such omissions can occur. In effect, therefore, on the gynaecological division, in Case I the patient died of acute, renal complications, an exacerbation of a chronic nephritis, as shown by the large increase in albumin, from a trace before operation to five per cent. by volume on the third day after, and the steady continuance of the acute condition to a practically complete suppression—only two ounces on the tenth day and death on the eleventh day.

The operation (anaesthetic) was clearly a contributory factor.

Case II. In this case the renal complication was not set down in the diagnosis-heading and history of the patient, and this is a serious omission; since, unless the histories had been carefully investigated by Dr. Creevey, the percentage of deaths from renal complications due to the anaesthetic would have been reduced one half.
The history shows normal urine on the day of operation.

Two days later there was five per cent. of albumin, granular casts, and blood in the urine—indisputably an acute congestion of the kidney on the second day. A broncho-pneumonia developed after operation. This was noted in the history heading, but not the kidney complication, as heretofore observed.

A case of an adult, with normal urine before operation, whose urine on the second day after operation shows five per cent. by volume of albumin and blood and casts, who has a broncho-pneumonia and dies on the third day following operation from suppression of urine, would seem rather a good illustration of the effects of an anesthetic on the kidneys.

The average clinician would, we believe, state the cause of death to be "acute congestion of the kidneys" and "pulmonary edema."

We have all seen in acute renal attacks, or in acute exacerbations of an old chronic nephritis, cases in which the pulmonary edema was not general but circumscripted; and in effect such a condition gives us the physical signs of a broncho-pneumonia.

It seems impossible to attribute this death to any other cause than to the effect of the anesthetic (ether) upon the kidneys. It further demonstrates that in the study of statistics mere compilation from history headings is insufficient; but that a careful study of each history is necessary, since such important omissions can occur.

We trust we may be able to therefore demonstrate to you by these results the necessity for adopting a uniform and, we believe, a scientific method for investigating the effects of anesthetics on the renal function in all cases in the hospitals you attend. Thus on the gynecological division of Roosevelt Hospital out of twenty-two deaths that followed operation two are fairly attributed to the deleterious effects on the kidneys produced by the anesthetic (ether), giving us nine per cent. as a death-rate from this cause.

To Tabulate.

The general average, 5.5 per cent., of deaths following operation, and due to the effect of the anesthetic (ether) producing fatal albuminuria through its specific action on the kidneys, is certainly significant. This occurs at Roosevelt Hospital, where there are skilled surgeons, most modern operating rooms—in fact, they are exceptionally fine—and with all possible precautions. Special care is observed as to avoiding exposure of the patient and in the administration of anesthesia; in fact, an expert anesthetist is at times employed, exclusive of the regular staff, and in every way care is observed. For example, on the gynecological service, where the percentage (nine per cent.) from the anesthetic (ether) as a factor in the fatal albuminurias existed in the year 1898 just passed, one can see all precautions taken, the limbs covered with specially made flannel and rubber-coated stockings to avoid wetting or chilling the patient, rapid and perfect technique, and the very avoidance of "lectures" during the operation, as were previously alluded to. Yet we have the figures, and the records are open to inspection. Who can hereafter deny the influence of the anesthetic in the production of renal symptoms with a resulting fatal issue?

Effects of Ether on the Kidneys.

Statistics gathered from cases operated on at Roosevelt Hospital between October 24, 1898, and December 31, 1898, by Dr. Creevey, house surgeon. Repeated through his courtesy by permission of Dr. Charles McBurney, attending surgeon.

* Decrease in one case due to removal of pus kidney.

Note.—Minus sign after per cent. means minute fraction less, as 59.8 — per cent. = 59.799 per cent.; plus sign, the opposite. Total cases of albuminuria due to etherization, 65.8 per cent. in 97 cases in which ether was administered. Dr. Robert Abbe reports that in 1,500 cases of etherization in St. Luke’s Hospital about fifty per cent. were followed by albuminuria. He believes this condition to be transitory. Since the quantity of the anesthetic and the method of administration have a bearing on the effects produced on the kidneys, the choice of the proper cone would be of importance. The old method of the towel and newspaper should be abolished, though it is still employed to a greater or lesser degree in many of our hospitals. A scientific inhaler, employing the minimum quantity of the anesthetic to produce the required anesthesia, should be used, such as Ormsby’s or Dawbarn’s, a recent improvement. The remarks made above apply to ether as used by these methods.

The New York Academy of Medicine’s Discussion on Anesthesia.*

By W. H. Thomson, M.D., LL.D.

The question of the comparative safety of the different anesthetics is much more uncertain than the results on the operating table itself would seem to show. The rapid and sometimes almost instantaneous deaths which are reported nearly every week in the English
medical journals as following upon the administration of chloroform put that anaesthetic at a great disadvantage in comparison with ether, for nothing can surpass such catastrophes in their terrifying suddenness. But if it can be argued that deaths follow upon the administration of ether quite so often, but only more slowly than after chloroform, the question then changes to a consideration of the specific derangements of vital functions caused by these anaesthetics respectively, and not until this is fully done can they properly be compared as regards safety.

The experimental researches originally made by myself and Dr. Kemp on the effect of ether upon the circulation of the kidneys seem to demonstrate that ether inhalation can cause in healthy kidneys acute renal suppression as complete as in scarlatinal nephritis. All the stages, beginning with oliguria, then albuminuria, then hematuria, and lastly, stoppage of secretion, developed with constant regularity according to the amount administered and the duration of the anesthesia. Therefore I can not see how we can expect to escape the occurrence of complications due to this specific action of ether upon the kidneys in many patients whose kidneys were not healthy before the operation. Such persons are not apt to die upon the table, as so many do with chloroform, for fatal renal derangements do not often act in that fashion. Pulmonary edema with bronchial effusion and aspiration pneumonia are much more likely to occur, and may take some days to run their fatal course. That such accidents are caused not infrequently by ether anesthesia I have no doubt whatever. Hence I regard that chronic renal disease, or the presence of any of the systemic signs of renal inadequacy, rigid arteries, high-tension pulse, and dilated right heart with chronic bronchitis, are all contraindications to the use of ether, and if any general anaesthetic has then to be employed, it should be chloroform instead.

The difficulty in deciding about chloroform is that in spite of the great amount of scientific inquiry on this subject no satisfactory explanation will cover all cases of fatality by it has yet been reached. In our own experiments the only result was a uniform depressant action upon the heart, as indicated by the carotid tracings. But that was in no way different from the effects of other cardiac depressants, whereas when chloroform kills it does so in ways that seem very special and by no means uniform. Sometimes in many well-recorded instances in the human subject the heart stops beating first and sometimes the respiration first, and these respective cessations are both so marked and prolonged that there can be no mistake that at times chloroform is a pure cardiac and at others a pure respiratory paralyzer. But in neither case does chloroform act invariably in the same manner. Thus, in cases where the respiration ceases first, we have Richardson's epileptiform syncope, where a tetanic rigidity of the respiratory muscles occurring before general muscular relaxation causes interference with the pulmonary circulation with venous engorgement, and lastly stoppage of the heart. Or, secondly, after general muscular relaxation has developed, death sometimes occurs suddenly from stoppage of the breathing, while the heart continues to beat. On the other hand, there are those more common cases where, after a few whiffs have been inhaled, the patient turns deathly pale and the heart stops as if it were pierced. Or, again, Dr. Lauder Brunton explains some cases of death from chloroform during operation as due to imperfect anesthesia failing to prevent the reflex effect of the shock of the operation while the anaesthetic has been sufficient to depress the heart itself. These different results, with the different hypotheses to explain them, serve only to show that with all its advantages chloroform can not be termed a safe anaesthetic, except in certain functional conditions of the nervous system. We say this simply because it is the verdict of experience on a great scale, and nothing but experience would prove this, for it is experience without any explanation. Thus chloroform has been administered in hundreds of thousands of cases in military surgery the world over without an accident. Almost the same thing can be said of its administration to women during labor, at least so far as the heart and respiration are concerned. But given before the heart is excited by the battlefield or by parturition, as when a patient dreads the trivial extraction of a tooth, and it may kill at once. I know of only one condition in ordinary medical practice in which I would feel quite easy with chloroform, and that is when a regular but high-tension pulse is present. A regular high-tension pulse, among other things, means a heart roused to work, and which will not easily be depressed, even though profound coma and convulsions are present. A weak, compressible pulse, on the other hand, decidedly contraindicates chloroform, especially in patients deficient in "nerve." Here we may add that, in general, the contraindications to chloroform furnish indications for ether. In our tracings ether as uniformly showed a stimulant action upon the heart as chloroform showed the opposite. A small, weak, compressible pulse grows fuller and stronger under ether. On the other hand, a habitually high-tension pulse is suggestive of kidney derangement from one cause or another, and ether will but add to that derangement and its results.

The fact that all agents or mixtures which produce anesthesia by inducing narcosis are in some cases very dangerous imparts great interest to the recent improvements in the methods for producing local analgesia which have been employed lately with complete success even in some major operations. It can not be claimed for them that they can supersede chloroform or ether for most operations, but, as I have seen the procedure tried upon private patients of my own by my surgical assistant, Dr. Kemp, in excision of an exceptionally serious carbuncle on the back of the neck in a
patient with damaged kidneys, also a large sebaceous cyst on the shoulder, and in operating upon a tuberculous elbow joint, without the slightest complaint of pain on the part of the patients, it is my opinion that no surgeon can afford now to neglect learning the technique or details of this method. One case so operated upon is quite sufficient to substantiate this statement. The patient was sixty-six years of age, greatly broken down in health, with an abscess in the kidney consecutive to cystitis and enlarged prostate. Lumbar colotomy was performed with an incision four inches in length and the kidney incised, the pus let out, and perfect recovery followed without the patient complaining of any pain during or after the operation, which lasted an hour and a quarter. Here the general condition of the man and the state of his kidneys contraindicated a general anæsthetic of any kind, and particularly ether.

To insure success by this method, however, the following details should be strictly followed:

1. An elastic bandage should be applied whenever possible, even about the scalp, as Dr. Leonard Corning long ago showed its promotion of the analgetic effect of cocaine, but care should be taken not to apply it too tightly, and also that it be loosened gradually after the operation is well over.

2. The cocaine or eucaine to be employed should be dissolved in a saline solution of a definite strength. This is an important part, for infiltration by pure water, on the one hand, or by too dense a saline fluid on the other, produces much pain by deranging, though in opposite ways, the normal osmosis of fluids in the interstitial spaces. Dr. Braun, of Leipsic, has worked out the proper strength of saline solutions for this purpose and puts it at 0.8 to 0.9 per cent. of chloride of sodium, which should be at the body temperature when injected, and not cold. The original Schleich formula was too weak in its proportion of cocaine and required too much fluid, so as to cause an artificial edema, while the addition in it of morphine does not add anything to the analgetic effect. A standard solution instead may be made of two grains of cocaine hydrochlorate in half an ounce of sterilized 0.9-per-cent. salt solution, of which one drachm will contain half a grain of cocaine. More than this amount of cocaine should not be used at any one time, and much less of it will be amply sufficient for most advisable operations. Eucaine has some decided advantages over cocaine in being only one fourth as toxic, though quite equal to it in analgetic properties, while its solutions can be sterilized by boiling, which destroys cocaine. The best strength of the solution of eucaine is one per cent., and, as it is so much less toxic than cocaine, more of it can be used.

3. The skin should be benumbed for the initial insertion of the needle by the cold of the ether or ethylchloride spray, or by ice, and then a ring of infiltration should first be made around the part to be incised by injecting at the outer limit until a wheel of infiltrated skin is raised; then a second wheel is made in the same manner by the needle being introduced at the edge, but within the circumference, of the first wheal. By this means the prick of the needle will not be felt, and the infiltration can thus be carried around the whole of the seat of the operation. Lastly, the line of the proposed incision is infiltrated and the cutting begun. On going further a weaker solution may precede the deeper dissection, and be resorted to whenever the patient begins to feel pain.

Now this process requires time, and unless that is given failure to produce complete analgesia is certain. Such operations, therefore, should not be done at clinics, for the operator is sure then to be too much in a hurry. But with the precautions mentioned such operations as radical cures of hernia, abdominal laparotomies, etc., have been performed without any suffering whatever.

The contraindications of such operations are where the edema caused by the infiltrations would interfere with the subsequent coaptation of the parts, as in plastic operations, also in most operations about the eyes, nose, or mouth, or in young children and in nervous patients, who might faint at the sight of blood. But in so many cases can this procedure be successfully employed without incurring any risk whatever that it is fully worthy to be classed among the important advances of modern surgery.

A CASE OF HYSTERICAL LARYNX.*

By F. E. HOPKINS, M.D.

SPRINGFIELD, MASS.

I AM led to present this case because it possesses some elements of entertainment, and it will not be amiss in so serious a programme to introduce an item of diversion. The case is also a rare one.

Miss V., fifteen years of age, a large, rapidly growing, anemic, nervous girl, but not appearing like a hysterical subject. She was ambitious as a student and took good rank in school. She was brought to my office September 25, 1897, because of a peculiar, not to say terrifying, spasm of the larynx. Aside from the symptoms connected with the larynx there were no hysterical manifestations. At the time of the school examinations of the preceding June she began to suffer from an attack of pertussis. The whoop in these paroxysms was much more marked than usual, and this increased in intensity so that by the middle of August the ordinary whoop was replaced by a high-pitched, piercing sound produced by strong inspiration with the vocal cords tense. It was a squeal—the squeal of a sizable and badly hurt pig. The cough ceased, but the squeal remained, and ultimately became both inspiratory and expiratory. The paroxysms were preceded by a sense of tickling and irritation in the throat, which caused first a slight cough, then followed the terrifying sounds. These occurred many times during the day,

* Read before the American Laryngological Association at its twenty-first annual congress.
though but rarely at night. Each paroxysm was followed by an interval of perfect rest. Examination revealed no local excuse for such explosions. There was a small mass of adenoids and some lymphoid hypertrophy at the base of the tongue. It seemed possible that the latter might induce some congestion of the larynx, but I regarded the case as hysterical, gave a favorable prognosis within the patient's hearing, and said if she did not improve we could burn the redundant tissue at the base of the tongue. The use of the laryngoscope, the favorable prognosis, or the promise of the hot electrode made a proper impression, for the paroxysms ceased, and for a few weeks did not return. November 6th she was brought back because of a recurrence of the spasmodic seizures. The galvano-cautery was applied to the base of the tongue, and this also was followed by an interval of improvement. Paroxysms began again suddenly and severely on March 1, 1898. So violent and continuous were they at times, the family physician informed me, that general anesthesia had been resorted to on three occasions, all other means having failed to control the seizures. I can, perhaps, give you no more convincing proof of the horror-producing effect of these earthy sounds than to say that they frightened a traveling drug vender from my waiting room.

On March 18th she was taken to the New York Postgraduate Hospital, where she came under the care of Dr. G. M. Hammond. He considered the case as probably hysterical; yet, because of the absence of the stigmata of hysteria, the sudden onset and termination of the symptoms, and the facts that the paroxysms were always limited to the same set of muscles, and that there was always a distinct interval of rest between the seizures, the case resembled one of convulsive tic, and he prescribed fluid extract of conium in increasing doses, which she took up to fifty minims three times a day together with morphine sufficient to keep her from completely depopulating the ward. She remained in the hospital but a few weeks, though continuing the treatment for four months, utterly without avail. During the later part of this period the family physician advised spraying the throat with cocaine solution, and this for a time appeared to shorten the attacks. On September 30th she was brought to my office, and while there had several violent seizures, which quite demoralized business for the time. Determined to give the larynx as well as the community a rest, I intubated, and though the tube—a medium-sized adult tube—was retained less than an hour, the result was indeed a happy one. It seemed just the suggestion needed, for there has been no recurrence since, and the patient's general health has greatly improved.

**RECURRENT OF THE TONSIL AFTER EXCISION.**

By F. E. HOPKINS, M. D.

SPRINGFIELD, MASS.

No monograph has appeared upon the subject of recurrence of the tonsil after excision, and what I have to offer may perhaps be regarded as curious and interest-
HOPKINS: RECURRENT OF THE TONSIL AFTER EXCISION.

Dec. 2, 1899. | S13

The trophied tonsil in form and size. There were, however, cicatrizes caused by the earlier operation. Dr. Wright examined the specimen and pronounced it simple hypertrophy.

When I was gathering material for a paper upon recurrence of lymphoid tissue in the nasopharynx, Dr. Emil Mayer kindly gave me some notes and incidentally mentioned a case of recurrence of the tonsils which came under his notice. I do not know that microscopical examination was made in this case, nor that the patient was free from specific taint.

The Journal of Laryngology, Rhinology, and Otology for August, 1898, makes mention of a case of recurrence in a young woman. The patient's history showed that she was tuberculous and had suffered from specific infection.

Burnett,* speaking of excision of the tonsil as a remedy for the relief of deafness, says: "I am furthermore convinced of the futility of the excision of tonsils for hardness of hearing, because the largest tonsils I have ever seen were the successors of excised ones. They might almost be regarded as recidives of a morbid growth."

John Nottingham,† having related a case of amygdamalotomy for deafness, states that "there has been no new growth on the side where the operation was practised." Further on he says: "Unfavorable occurrences may follow such an operation (amygdalotomy) if the cases for its practice be not judiciously selected. One is a second or new growth of the part operated upon. A patient may have his tonsil excised, and in less than twelve months' time the tumor on the side of the throat may be found prominent, spongy-looking, and as large, if not larger, than before. This seldom occurs except in patients of strumous constitution, and may, in some instances, be averted by the employment of the solid nitrate of silver applied daily for some weeks after the operation."

J. Mason Warren,‡ in his paper on excision of the tonsils, read before the Boston Society for Medical Improvement, does not mention the subject of recurrence, but in the discussion which followed his paper he was asked whether the tonsil had ever been reproduced after excision. He replied that he had been obliged to repeat the operation four or five times in about five hundred cases. Homans, in discussing the above paper, said he had two cases in which the operation had to be repeated. In one of these the operation, while thorough at first, required to be repeated five years later. In the other case, in which both tonsils were removed, one was now again in condition to require removal.

Stapleton,* in the discussion of a paper by Martin on amputation of the tonsil, said he had known of cases

* Diseases of the Ear, 1884, p. 40.
‡ Boston Medical and Surgical Journal, 1857, vol. ivi.
* Dublin Medical Press, April 19, 1863.

where it was necessary to remove the tonsil more than once. It might be urged that removal had not been thorough, but in his experience the cases were examples of pure reproduction.

Ruppaner,* in enumerating popular objections to cutting, includes this one; that "the tonsils after being cut grow again." He remarks: "Strangely as it may seem, this claim is often made on the authority of the family physician."

W. H. Daly says: † "As to the question of the liability to grow again, the answer can be included in this remark: that with every badly treated or neglected cold affecting the throat there will be some tendency for the tonsils to increase in size again; but this tendency is not marked by any means, and may be prevented altogether with ordinary care and proper treatment by local applications."

W. Porter says: ‡ "It has been urged as an objection that there may be recurrence of the hypertrophy. In over a hundred and fifty cases I have had to do a second operation but twice, and in one of these cases the operation had not been thorough. As hypertrophy is largely due to retained secretions, it seems reasonable to believe that when the crypts are removed hypertrophy can not take place."

J. G. Carpenter,* in a paper read before the American Rhinological Society on the abuse of uvulotomy and amygdamalotomy, speaks of the common practice of removal of the tonsils, and says that as tonsillar disease is kept up by nasopharyngeal catarrh, hypertrophied tonsils will enlarge again and again after removal until this catarrh is cured.

Behrens,|| in the course of an article on one hundred and twenty-seven amygdamalotomies, says: "As to the common pretext that tonsils operated upon again hypertrophy, this is not valid with physicians of experience. Even if they do return, it is no argument against operating."

Lennox Browne says: * "Very rarely indeed is there a redevelopment of the hypertrophy; but as such a circumstance is not outside of my experience, I always endeavor to remove as much of the gland as may be pressed into the guillotine." The above would appear to be the only mention of the subject of recurrence of hypertrophy in any standard work which includes diseases of the tonsils.

The following controversy between B, an anonymous contributor to the Medical Times and Gazette,

† Medical Record, February 10, 1883. Paper entitled Some Questions relating to Tonsillitis.
|| Western Medical Reporter, January, 1889.
The foregoing represents all that could be found in the library of the New York Academy of Medicine and of the surgeon-general's office at Washington. It is seen that a wide variety of opinion is represented as to the frequency and cause of recurrence, as well as of its prevention. We can not accept all the conclusions of the various writers, but the facts observed are none the less of interest to us. It is noticeable that few cases are alluded to by laryngologists, and that most of the references are of cases which were published some years ago. The inference is that under general anesthesia, now so commonly employed, a more thorough operation is performed and recurrences must be even more rare than formerly.

It would appear that among the causes of recurrence, aside from imperfect operation, are a tuberculous or specific dyscrasia and an acute inflammation of the stump. It would naturally be supposed that this acute inflammation of the stump must take place soon after operation in order to result in recrudescence of the tonsils, as occurred in my own case; yet Mackenzie mentions a recurrence following acute inflammation long after operation. My purpose is served in simply calling your attention to the subject, and I refrain from more extended comment.

DRY HEAT OF HIGH DEGREE AS A THERAPEUTIC AGENT.

By C. E. SKINNER, M.D.,
NEW HAVEN, CONN.

(Continued from page 780.)

In malarial disease we always find a marked impairment of the liver. Now, an impaired liver will throw into the blood current more nerve-depressing products of faulty metabolism than any other organ of the body except the impaired kidney. When the steel has enveloped the wood, then we are brought to bay by a problem consisting of three parts: first, the parasite safely seconed in the blood-capuscele; second, the nervous debility resulting in metabolic impairment which struggles assimilation; and, third, the impaired liver, the faulty metabolic emanations from which, in company with the ptomaines constantly being produced by the micro-organisms, maintain the nervous debility and its own impairment.

The first step, then, is to effect the regeneration of the liver in whole or in part, at the same time maintaining an adequate saturation of the blood by quinine. If we can regenerate it only in part, then the nervous system will be partly relieved, and through it the metabolic activity partly reestablished, and the red blood-corpuscles will be able to absorb a little more of the quinine and get a little better grip upon their antagonists. Calomel is a poison which exercises one of its elective-tissue affinities upon the liver cells, and theoretically
would seem to be a good agent for this purpose. Practically, when properly given, it rarely disappoints us.

Now, if, in addition to removing a portion of one of the factors which is maintaining nerve depression, we can also directly stimulate the nervous system to aid in its own regeneration, we shall have given the over-whelmed metabolic functions a good big pull toward the surface, and thereby have increased by a vast deal the power of the red corpuscle to wield its weapon over the parasite. Strychnine is a drug which stimulates nerve tissue en masse, and, as the welfare of the whole increases the welfare of all the parts, the administration of this remedy in addition to the cholagogue will in most cases enable the red blood-corpuscle to metabolize the quinine sufficiently well and in sufficient quantities to effect the destruction of the parasite, and with the consequent cessation of ptomaine production the nervous system is able to regain its tone and recovery follows.

Not always, however. The impairment of metabolism is occasionally so great that arsenic, a drug which stimulates directly primordial protoplasm itself, will have to be resorted to before the corpuscles can develop enough assimilative energy to use effectively the instrument of their salvation. Although quinine occasionally needs the aid of all these contributing agents in curing malaria, yet no one thinks of attacking its claims to specificness in this disease, and this is as it should be. The fault is not with the remedy, but with the conditions under which it is required to act.

In rheumatism, as in malarial disease, we have a special materies morbi which elects special tissues as most suitable for its habitat, and these are the white fibrous structures about the joints and heart, and the muscles. The ptomaines in this disease, however, do not exert anything like the same profoundly noxious depression upon the general nerve centres, and hence the general bodily metabolism is not nearly so badly impaired. The local metabolism in the tissues about the lesion suffers, however, and occasionally suffers so profoundly that medicine, however specific against the rheumatic micro-organism, can not be assimilated by the cells in which it has established its abode in such a manner and quantity as to effect its destruction; hence a large number of cases exist in which the salicyl compounds have been inefficient. This is where the powers of hot air are manifested.

As we have seen, this is also the case in malarial disease, where quinine alone sometimes fails. In this latter disease, however, the impairment of metabolism is general, involving tissues which, as well as the seat of primary infection, the corpuscles, are susceptible to the influence of contributing agents which have long been known as tonics, three of which we have mentioned, and thereby almost invariably a radical cure of the disease has been secured. In rheumatism, as distinguished from malarial disease, the impairment is only local, and because of the peculiarities of the tissue affected it possesses a nature peculiar to itself, and hitherto no effective contributing agent had been discovered which would act efficiently upon these particular specialized cells. No wonder that failures were common. This occasionally present need of a contributing agent may be construed as another point of analogy between the two diseases.

Then, again, rheumatism is a much more frequent affection than malarial disease, and even though the proportion of salicyl failures were not larger than that of quinine in the latter, yet the whole number would be larger and the rheumatic specific would apparently compare unfavorably with its malarial relative. In addition to this we must remember that many an illness is diagnosed as malarial, and the patient recovers while quinine is being administered, which is not malarial at all, and the remedy thus secures a vast deal of credit which it does not deserve. I recall no painful affection which would be likely to be mistaken for rheumatism and which salicyl compounds would be effective in curing, so that there has been little danger of the rheumatic specific receiving more credit than justly belongs to it.

Until the introduction of salophen this specific was obliged to make a single-handed fight, unlike its analogue quinine, no contributing agent of any value being known. Salophen at the present time is the only drug adjunct available which combines powerful analgetic with marked antirheumatic properties, but it leaves much to be desired. Phenalgin is most powerfully analgetic in this affection, as it is in almost all others exhibiting painful phenomena, as are also in a lesser degree other derivatives of its class, but none of them or their combinations seem able to exercise an eradicating influence upon the disease equal to the salicyl compounds.

My experience with hot air, however, has led me to believe that we are about to turn a new leaf in the history of the results of rheumatic treatment, and that this potent contributing agent will raise salicin to a rank as an antirheumatic specific in no wise second to quinine as an antimalarial one. I specify salicin as distinguished from salicylic acid and sodium salicylate because the two latter possess irritant tendencies toward the stomach and kidneys and depressing tendencies toward the heart, which sometimes render their ingestion in sufficiently large doses pregnant with disadvantageous effects upon the patient, and salicin is entirely free from these and usually just as effective.

It is in proving the effectiveness of the salicin regimen, when conditions hampering its action are removed by a sufficiently powerful contributing agent, that hot air forges another link for the analogical chain.

In promoting the absorption of the fibrous growths which sometimes remain and serve to keep up pain upon movement in joints previously affected by rheumatism, the measure under consideration is of great potency. It
is worth while to bear in mind the fact that many cases of so-called chronic rheumatism consist of nothing more or less than these relics of former inflammations, and I have never seen any medicine afford more than the most temporary sort of relief. Deep septic foci, the various neuralgias, periositis of diverse atiology, masked gout, joint inflammations other than rheumatic, and, rarely, pressure from some tumor, also deserve a larger share of attention during our diagnostic deliberations in this connection than is usually accorded them, but the scope of this article permits merely their mention. Hitherto our only resources where fibrous adhesion has obtained have been massage and passive movement, electricity, blistering, and forcibly breaking down the bands.

The first two of these procedures have the largest proportion of good results to their credit, but absolute absence of any but very transitory benefit is not uncommon, limited results only obtain in the majority of instances, and a perfect removal of the evil is secured in only a very few. Blistering, to be effective, must be severe and sometimes frequently repeated, and its disadvantages, among which the discomfort caused the patient is not the least, need only be mentioned to be appreciated. Forcibly rupturing the adhesions is theoretically the most radical and effective method of eliminating this element in the equation; but the practice is commonly followed by reparative efforts of the parts, which become excessive and result in the formation of fresh adhesions, necessitating repetitions of the operation, to say nothing of the extreme pain caused to the patient, which usually is severe enough to demand an anaesthetic. And even then our results are many times open to criticism, and often to severe criticism, both as regards joint mobility and subsequent relief from pain on movement. The agent I am advocating usually renders any of these other measures unnecessary, and in those cases where it is not sufficient forcible rupture of the adhesions, the most radical, effective, and quickest of them, can be safely and confidently employed, because the hot air, applied immediately before and after the operation, relieves the pain very effectively and strangles the excessive local inflammatory reaction at its birth.

Another instance of its happy effect upon local inflammation is exhibited in its power over the unpleasant consequences of a sprain, which is strikingly illustrated by the following:

Case V.—Mr. F. A. G., professional man, about thirty years old, residing in a neighboring city, was in New Haven on a flying business trip in December, 1898. He had occasion to go upon the roof of a building, which was slippery, and slid off from the eaves, falling a distance of about twelve feet, alighting with great force upon his buttocks, with his right ankle doubled under him. Was rendered insensible by the shock, and on recovering consciousness discovered that among his numerous other aches and pains that caused by move-

ment of the injured ankle was the most excruciating. I saw the case about four hours after the accident, at which time the ankle had begun to swell quite rapidly, was throbbing painfully and incessantly, and any manipulation caused the sufferer to shriek with agony. Hot air was administered early that evening, with resulting relief of the painful throbbing in twenty minutes. Patient complained several times during treatment that his toes were "burning," but the sensation was relieved by pressing the towel down firmly upon the complaining members. He was put to bed with directions to call me at once if the pain returned, but no strapping or bandaging was applied. The joint was left perfectly bare and free. He was very anxious to get back to his home the next day, but I did not think it would be possible.

I heard nothing from him during the night, and on calling the next morning ascertained that he had fallen asleep shortly after I left, and had remained so all night. Ankle was not at all painful except upon movement, and then the sensation was that of exquisite soreness instead of the sharp, tearing agony of the night before. The swelling had nearly all disappeared, but the joint was still very tender upon deep pressure. Upon the end of the second toe was a blister the size of a split hazelnut, due to my inability to envelop the toes with the wrappings as closely as was desirable because of the extreme pain from even the slightest movement of the joint. Perspiration had collected upon the exposed area of skin, and my pressures had not been frequent enough to remove it before it had reached the boiling point, with the result, as the victim remarked, that "this morning the effects of your treatment are nearly as bad as the disease." He was extremely willing to submit to another, however, and was able to hobble unaided from his bed to another room wherein was the apparatus.

At the conclusion of this treatment patient again spoke of his desire to get home that day, and I told him to go in the afternoon if he felt able, but, if he did, to send me word, as I desired to treat him again in the evening if he were in town. He left that afternoon, and wrote me a few days later that he had reached his home with comparatively little trouble, so far as his ankle was concerned, and that the following day had been marked by the return of his ability to use the joint as freely as ever without pain or stiffness.

Formerly I had been in the habit of relying upon Dr. J. L. Crook's modification of Dr. Gibney's method of strapping with adhesive plaster, as detailed in the International Journal of Surgery for July, 1896, in dealing with sprained ankles. This had given me better results than any other treatment. But hot air is as much better than this as this is better than the others.

I was led to extend my experiments into the field of acute diseases other than rheumatism of microbial origin by the following experience:

Case VI.—Miss I. L., waitress. Was called to see the patient at two o'clock A.M., November 8, 1898, and found her suffering with severe colic. Had been feeling poorly and suffering from slight cramps in bowels for a week past. Abdomen was tense and tender, this last being especially well marked in the left iliac fossa. Bowels had been constipated for the past week. Pulse, 72; temperature, 98.6° F. Made provisional diagnosis
of colic from indigestion and constipation, but, as patient was living in illicit relation with a man about town, and as I had met with some trying surprises in the way of gonorrheal salpingitis, peritonitis, and intractable appendicitis during my practice, I decided to call again and watch her progress. Administered morphia, a quarter of a grain, and ordered magnesium sulphate in teaspoonful doses hourly, to be begun in the morning and taken until bowels moved, and then discontinued. Patient was comfortable, so far as pain was concerned, in half an hour, and I returned to my couch and resumed my interrupted slumbers.

**Same Day, 6 P. M.**—Found patient suffering acutely from severe cutting pains all over abdomen; pulse, 106; temperature, 100.5° F. Abdomen tense, acutely sensitive to touch, but focus of tenderness still remained in left iliac fossa, which was entirely intolerant of manipulation because of it. I was unable to find anything specific in the neighborhood of the appendix, changed my diagnosis to gonorrheal salpingitis and general peritonitis, and was glad that I had called again. Morphia had controlled pain pretty well for four hours, after which it had returned, and continued with increasing intensity up to the time of my visit. Magnesium sulphate had produced two small, thin movements accompanied with sharp pains. I made up my mind that I was in for another of the usual harassing experiences which constitute the treatment of these cases, ordered that flannels wrung out of hot water be constantly applied to the abdomen, as hot as could be borne by the patient, gave her another hypodermic, left her two-quarter grain morphia pills to be taken in case the pain became unbearable, and put her on an exclusive milk diet.

**November 9th, 12 M.**—Patient had been suffering intensely since midnight. Knees were drawn up, abdomen much distended, unable to make the least movement without provoking excruciating agony, which was also occasionally exacerbated by attacks of retching, which accomplished nothing. She was shivering and her teeth were chattering from the exhaustion due to long-continued suffering. Pulse, 101; respiration, 28, very shallow and quick; temperature, 101.2° F. The morphia pills that I had left had not been used, as I had requested her not to take them unless it was absolutely necessary. With the proverbial capacity of her sex for enduring pain, she had not considered that the point of absolute necessity had yet been reached. I saw that something had to be done or the exhaustion from this continuous terrible pain might kill her of itself. I hated to inaugurate a systematic course of morphia, with its resultant evils, particularly undesirable in a disease of microbial origin, where it is of the first importance to preserve the metabolic activities of the body unimpaired, but, as the hot applications were doing practically no good, it seemed the only measure capable of dealing with the situation.

While I was considering, the attendant came to the bedside to change the flannels. The patient looked up at her and exclaimed, "Oh, is it very hot?" Upon being assured that it was, she remarked, "The hotter you give it the better it feels."

Like a flash my hot-air apparatus rushed into my mind. With it I could apply a heat of 500° F., whereas the flannels could not be used at more than 160° F. I quickly asked her if it was true that the greater the heat the greater the comfort she experienced. She answered that if the flannels were not very hot they gave her no relief at all. A small ray, that was hardly strong enough to hope, brightened the darkness. If 160° F. of heat gave her some relief from pain, twice or three times that might give her a good deal, and by frequent repetitions I might be able to avoid the morphia. It was worth the experiment. I told her that I would try something else in the afternoon and did not administer any morphia.

At 4:30 I applied hot air with doubt, fear, and trembling. My gratification can be better imagined than described when at the end of ten minutes the sufferer's face relaxed its pain-distorted lines. In thirty minutes she looked up at me with a quiet smile, saying, "Oh, how good that feels!" and in forty-five minutes, while still under treatment, she had fallen exhaustedly asleep for the first time in thirty-six hours.

At the end of treatment patient expressed herself as being entirely free from pain while she kept still, but when she moved it was still there, and manipulation was as little tolerated as before. I left the apparatus there, directed that I be called immediately when the pain returned, and departed, walking upon air, because of the result achieved. I expected, of course, that a repetition would soon be necessary. However, I had been able to give her a relief so perfect that even morphia would have been inadequate for its accomplishment, and by withholding the drug had been enabled to preserve her mental and physical functions unimpaired. If I could keep this up I would be willing to treat her every hour if necessary. The hours wore on, and to my growing astonishment I received no summons, until by the following morning I began to fear that another physician had been substituted for me without the formality of my discharge having been observed. I found it difficult of belief that the treatment could have produced results so happy and so long continued.

**10th, 12 M.**—Patient greeted me smilingly, reporting that relief from pain had continued complete until nine o'clock the preceding evening, when for about fifteen minutes she suffered from slight cramps. At midnight she had severe cramps for an hour, but none since, and to make a long story short, I will say here that those were the last pains she suffered. The abdomen was relieved of its distention; tenderness upon pressure had entirely disappeared from the right abdomen, but was considerably in evidence in the left, and very much so in the umbilical region and below, from manipulation of which she shrank in terror. Bowels had functioned spontaneously and with little pain. Was taking milk freely and stomach was not at all irritable. Pulse, 72; respiration, 18; temperature, 98.6° F. Hot air was again administered.

**Same Day, 6 P. M.**—Patient was and had been entirely comfortable. Pulse, 83; respiration, 18; temperature, 99° F. Directed that I be called if pain appeared, and did not see her again until the next day.

**11th, 10 A.M.**—Patient had slept uninteruptedly all night and was feeling hungry. No tenderness anywhere in the abdomen except over a small area immediately inferior to the umbilicus. Pulse, 78; respiration, 16; temperature, 98.6° F. Hot air administered.

**Same Day, 9 P. M.**—Patient has been sleeping some during the day. Entirely comfortable and only very slight tenderness on pressure in umbilical region. Pulse, 66; respiration, 18; temperature, 98.6° F.

**12th, 8 P. M.**—Found patient sitting up, dressed, sewing. No pain or tenderness upon pressure was any-

where discoverable. Pulse, 76; respiration, 18; temperature, 98.6° F.

15th, 8 P. M.—Patient called at my office as by appointment. Pulse, 78; respiration, 20; temperature, 98.6° F. Examination reveals slight tenderness upon deep pressure over left Fallopian tube. Nowhere else, Escorted her upstairs to my operating room and once more administered hot air. Requested that she report in three days.

18th.—Reports that she returned to her work yesterday morning. Feels as well as she ever did in her life, and searching examination betrays absolutely no sign of her late illness. She wrote me a letter from another city two months later in which she stated that she was and had been perfectly well since I last saw her.

The felicitous results which I had obtained in this case opened my eyes to the fact that the sphere of usefulness of hot air was by no means confined to rheumatic affections. If it would thus profoundly influence the peritonitis why would it not produce like results upon the pleura, and even upon deeper tissues, the air cells themselves? I soon had an opportunity to try the experiment.

CASE VII.—On November 8th, the same day upon which I first saw the preceding case, I was called to attend Mr. J. H., thirty-two years old, and found him suffering with pneumonia, another disease which I take special pleasure in treating. He had been steadily growing worse with what he thought was a cold for the preceding four days. Pulse, 84; respiration, 44; temperature, 102° F. By evening of the same day his pulse had risen to 88, respiration to 50, temperature to 103.5° F., and I decided that the trouble was grippe pathologically. The lower lobe of the left lung was the area exhibiting consolidation.

As the measure under consideration did not appear in the case until November 17th, I will not go into the details of the intervening period. Suffice it to say that on November 9th the sputa became typically pneumonia, which, in connection with other conditions then obtaining, induced me to change my mind as to its influzncial origin, and that after this the case progressed as these cases usually do. Resolution was taking place, and on the evening of the 16th of November I formed the conclusion that the illness would soon reach a happy termination, although the patient was much reduced in strength, and expressed my intention of not calling again until the following evening.

November 17th.—Was sent for in great haste at 6 p.m., and on arriving learned that the victim had begun to be troubled with his breathing again and to feel badly this morning, which symptoms had steadily increased up to the time of my visit. Had slight chill in the night. He was shockingly prostrated, suffered with severe pain in right side, had constant, tremulous, hacking cough, and was raising blood-stained sputa. Pulse 130, very weak, and irregular; respiration, 50, shallow, unsteady, and “catchy”; temperature, 101.2° F. Physical examination showed that the original focus of the disease was in a satisfactory condition, but that the lower lobe of the right lung was consolidated, and a marked pleural crack was evident. Heart sounds were very small and muffled.

Here was an encouraging condition of things! A patient who had not yet recovered from one severe pneumonitis, which it had required nearly all of his reactive power to overcome, saddled with another just as severe apparently as the original attack, and which he would have to fight not single-handed, but half-handed. I fully expected that the prescription I was then giving would soon be dispelled by a death certificate. Before despairing, however, I called to mind the possibilities suggested by the preceding case, and decided to test the capabilities of hot air in that direction.

Treatment was applied, and in thirty minutes patient was resting quietly, the cough was stilled, pleural pain had diminished in intensity to such an extent that he said he “didn’t mind it much now,” respiration was easy at 32 a minute; pulse 116, and so increased in strength and volume that the trained nurse in attendance remarked that she “had never seen anything act like that before.” I never had myself, although I did not say so, and my gratified surprise, though great, was not as profound as it would have been had this case superseded No. VI. In fact, I do not think I should have used it at all had such been the succession of events.

I had discarded pneumonia jackets, poultices, and other local applications in this disease five years previously, except in those cases characterized by severe pain from pleurisy, and then my local measures were confined to mustard plasters and the hot-water bag. I have never had the courage to use ice, either my experience nor any line of reasoning to which I have listened having as yet persuaded me that the oft-expressed belief in the identity of the effects of extreme hot and extreme cold applications is a well-founded one. It seems to me that to convince himself one has only to immerse his hand in water at 32° F., keep it there five minutes, and note carefully the effect and sensations produced. Then, after the member has fully recovered from this immersion, plunge it for the same period of time into water at 160° F., which is as much hotter than the normal as the freezing point is colder, and observe the difference. I can not conceive how any one who has ever seen the difference in the effect of hot and cold applications upon an incarcerated hernia can continue to believe their effect identical. Another refutation is met in the fact that in some individuals a neuralgia will be aggravated by cold applications and relieved by hot, and in others vice versa.

A long-continued contact with cold is extremely depressing both to the organism as a whole and to the local metabolism of the part acted upon, and I am opposed to its use in pneumonia, except to the extent of an ice-cap for cephalalgia, or when it becomes necessary to combat hyperpyrexia. True hyperpyrexia rarely obtains in this disease; however, as the strain upon the vital powers, which precipitates it by exhausting the heat inhibitory centres, is not sufficiently profound or continued long enough. The disease is usually characterized by a rapid crisis.

My mustard pastes and hot-water bags would give the patient considerable relief from pain, but I have
never observed that it was very marked or sustained, or that any radical effect was observable upon the local lesions. Of course not, because it was not hot enough to modify tissue metabolism with sufficient force or to penetrate to a sufficient depth. Pneumonia, so far as we now know, is a disease many, at least, of the pernicious features of which are due to ptomaine toxicity of microbic origin; hence, for the same reasons set forth in connection with its use in Case VI, I am opposed to morphine here. Thus the power of dry heat of high degree to relieve the pleural pain of this ailment was a source of gratification second only to that which I derived from its, as far as the life of the patient is concerned, more important power of influencing the engorged circulatory apparatus of the consolidated area, as shown by the marked and immediate improvement in the pulse and respiration.

I may say here as well anywhere that I have never seen any shortening in the duration of this disease, as regards its general constitutional features, through any influence exerted by hot air. The characteristic respiration, the considerably not greatly accelerated pulse rate, the variations in temperature, prostration, sweats, etc., obtain and run their courses much as usual, except that they may be somewhat mitigated in intensity. I am not prepared to make a positive statement even to this extent in this connection as yet. Its power is effective purely and simply against the local lesion, and probably whatever general benefit accrues is due to the relief of reflex disturbances and cardiac distention dependent thereon. In the cases which I have so far treated with it the exudate has disappeared, and, so far as physical signs would show, the pulmonary tissue has regained its normal condition in from three to five days. How much of a part is played by lessened ptomaine production, through this profound influence upon and rapid removal of the local pathology, in the general good resulting therefrom, I am unable to state. It certainly effects a vast increase in the patient’s comfort, which is an aid not to be by any means despised.

(To be continued.)

**Therapeutical Notes.**

**Bourguignon’s Ointment for Scabies.**—The formula, taken from the Bulletin général de thérapeutique, is thus given in the Indépendance médicale for October 25th:

- 2 parts; 2 parts; 4 parts; 30 parts; 90 parts; 180 parts.

The Permanganate Treatment of Gonorrhoea.—In the discussion of a paper by Dr. Motz, read at a recent meeting of the French Association of Urology (Presse médicale, October 25th), Dr. Guiard favored the use of weak solutions, not stronger than 1 to 5,000 or 1 to 10,000. They were quite as efficacious as strong solutions, he said, and produced neither pain, hematuria, nor “serious reaction.”

The Treatment of Pruritus.—In the Presse médicale for September 9th Dr. A. F. Plipec says that the two following applications are among the most efficacious. The first is known as Vital’s glycérolé tartrique, and the second as Hardy’s lait soufre:

1. B. Glycerite of starch 20 parts; Tartaric acid 1 part.
2. B. Emulsion of almonds 10 parts; Sulphur 1 part.

M.

To Cure a Cold in the Head.—Dr. A. S. Barnes (Interstate Medical Journal, October) gives the following directions: Place the patient in a bath of warm water, the temperature being from 97° to 100° F., or as hot as he can stand it without inconvenience for five minutes. Then roll him in a warmed blanket and put him in bed, heaping on covers. Something must previously be placed under the patient so as not to wet the bed clothes from the sweating. Next give one eighth of a grain of pilocarpine hydrochloride dissolved in one half glass of warm water. If the patient is weak or thin, less pilocarpine may be used. After three quarters of an hour’s sweating give the patient one-one-hundredth of a grain of atropine in water. Fifteen minutes after this mop him without friction with warm towels (the Turkish being preferable) and put on him a warmed night robe, placing him between warmed sheets with his ordinary covering over him. Give the following prescription:

- 18 grains; 46 “
- 4 “

M., ft. capsule xij. Sig.: One every two hours.

Be sure and inform the patient that the dripping from the mouth is the result of the medicine and will soon disappear.

If these directions, says the author, are carried out to the letter there is no danger connected with this treatment, and this method will cure a cold more quickly than any other.

**Mercury and Iodine in Syphilitic Affections of the Joints.**—Dr. W. Pielicie (cited in the Deutsche Aerzte-Zeitung for November 1st) gives the following formula:

- 14 grains; 75 grains; 2,700 “
- 300 “

M. S.: A tablespoonful twice a day.

Oil of Wintergreen as an Application to Suppurating Surfaces.—At a recent meeting of the Paris Society of Therapeutics (Indépendance médicale, November 8th) Dr. Gallois reported excellent results from the use of pure methyl salicylate (oil of wintergreen) as an application to various suppurating surfaces, including that of a varicose ulcer, a patch of furuncles, open cervical glands, and a subungual abscess.
THE PLAGUE-SHIP AND HER CARGO.

The newspapers, as was to have been expected, have been somewhat excited over the recent arrival at the quarantine station of New York harbor of a steamer having in its company two men apparently convalescent from the bubonic plague. This is only natural; the plague is a disease with which we are practically unacquainted, and therefore it has the terrors of the unknown. Few people in this community are much exercised over the matter of avoiding the infection of typhoid fever; indeed, most of them are obstinately deaf to the warnings that medical men are continually spreading broadcast. But let a new disease threaten us, or one that, though old in the world’s history, is one to which we are unaccustomed, and at once a panic is almost sure to arise. However, the world is growing more and more callous to the alarmist’s outbursts, and there are as yet no signs that New Yorkers are stirred up about the plague.

The question seems to be as to what shall be done with the ship’s cargo, consisting of coffee in bags. The health officer of the port, Dr. Doty, and his predecessor, Dr. Jenkins, both of whom are members of the city board of health, are understood to be in favor of allowing the coffee to be landed after a proper exposure to influences generally held to be quite adequate for the destruction of plague germs. We do not question that they are quite right in the stand they are reported to have taken, but perhaps it would be well to have the coffee roasted and put into fresh receptacles before it is brought to the city, if only to allay the fears of the few citizens who might otherwise become alarmed.

The ship’s rats are the real sources of danger. If any of them have made their escape to the shore and taken up their abode on board craft bound for the city, the consequences will be known before long; but the supposition that they have done so seems untenable in view of the disinfecting processes to which the ship has been subjected. We have no fear of the coffee and we are not afraid of the rats; let the cargo come to town.

gethers by a metal ring. This ring is pierced by two tubes and the cavity is filled by a current of cold water. The lens is strapped on to the part to be operated on, rendering it amnestic by the pressure and at the same time cooling it. If sunlight is used to concentrate the rays on the spot to be operated upon, a plano-convex lens formed of a flat plate of glass and a convex one, the space between them being filled with a bright blue, weak ammoniacal copper solution, is employed. By thus selecting only the blue and violet rays the chemical and bactericidal effects are more marked, while the burning properties are excluded.

When, however, the electric light is used, a different apparatus is needed, consisting of telescopic tubes with two quartz lenses at the proximal end, while in the distal end of the tube are two other quartz lenses, the space between being filled with distilled water. This tube is attached to a ring surrounding the area light in such a manner that the rays are concentrated on the spot to be operated on, the pressure-screen lens first described being interposed. The British Medical Journal for September 30th gives a very lucid description of the method from the pen of Dr. Valdemar Bie, Dr. Finsen’s laboratory assistant. Illustrations are shown of the various instruments, the methods of their employment are described, and four cases are related in which the patients are portrayed before and after treatment. The results would seem to be distinctly remarkable. Some three hundred and fifty cases of lupus vulgaris have been dealt with at the institute in two years, and in every case improvement has occurred, in all but five amounting practically to cure. There seem to have been no real recurrences, though small nodules, probably masked by the dermatitis, have occasionally escaped notice and have needed a second spell of treatment. Lupus erythematous and alopecia areata have also shown some remarkable results, though not such signal ones hitherto as have been afforded in lupus vulgaris.

Dr. Stephen Mackenzie, in the British Journal of Dermatology for November, details his experiences during a week at the Finsen Institute, and the impression formed by him was so favorable that he has prevailed upon the authorities of the London Hospital to adopt Finsen’s method, all the apparatus having been generously presented by the Princess of Wales.

The advantages claimed for the light treatment of lupus lie in the minimizing of the unsightly scar, the skin remaining smooth, soft, supple, and neither deeply pigmented nor deadly white. There appears to be no liability to recurrence or contraction. The application is said to be altogether painless, although in a case presented by Mr. Malcolm Morris to the Dermatological Society of London (British Journal of Dermatology, November) some pain appears to have been experienced on the first application. The treatment also does away with the natural dread of “an operation” and with the danger arising from anesthesia. There are, however, two considerable objections—the slowness of the process and the expense. The treatment requires to be continued during at least three or four months for a period of an hour daily. The apparatus is costly, much medical attendance is involved, the working cost of the electric light is considerable, and it seems that a special nurse is required for each patient during the treatment. Until some simplified methods have been evolved—as our experience with the X ray must lead us to think will quite probably be the case—the treatment will be inevitably confined to institutions.

At various times the effects of colored glass, sunlight, etc., have been insisted on as the basis of therapeutic systems. While we do not look for the establishment of any “system of therapeutics,” we certainly think that the Finsen phototherapy has introduced a new therapeutic method, and indicated a field for further investigation, signs of which are evident in a paper on The Therapeutics of Light and Heat, by Dr. W. Knowsley Sibley, in the British Medical Journal for November 4th.

STYPTICIN IN THE TREATMENT OF UTERINE HÆMORRHAGES.

The besetting sin of the gynaecologists of the present day—but one from which, we are glad to observe, they seem to be emancipating themselves—is the propensity to perform an operation if only a pretext for it can be found. As Dr. H. Abegg, of Dantzic (Centralblatt für Gynäkologie, November 4th), puts it, they are too apt to overlook the question, Would you have the operation done on your own wife? He cites the fact that many operations are performed for uterine myomata without any urgent reasons for them, and he gives it as his own opinion that, aside from malignant tumors, there is only one positive indication for laparotomy for uterine neoplasms, namely, the frequent occurrence of intractable hæmorrhage.

As to the medicinal treatment of uterine hemorrhage, Abegg gives his experience with stypticin in fourteen cases, including one of menorrhagia, three of defective involution of the uterus after abortion, one of hæmorrhage after labor at term, and nine of hæmorrhage at the menopause. He has not found stypticin efficient in cases of hæmorrhage due to large myomata or polypi, but in some of his cases it proved useful as a
EDITORIAL ARTICLES.

DEPARTMENT OF PUBLIC HEALTH.

We call the attention of the State Board of Charities to the provisions of the philanthropic acts. The wholesome conditions of the life of the people, as the result of a beneficent administration, is the object of every public institution. Whether it be the State Board of Charities or the State Board of Education, the object is the same. A wise and frugal administration of the charities of the State is a part of the education of the people. We cannot too strongly urge upon the Board of Charities the necessity of a careful examination of the charities of the State, and of a system of classification and a regulation of the same. We cannot too strongly urge upon the Board of Charities the necessity of a careful examination of the charities of the State, and of a system of classification and a regulation of the same.

Sedative, producing placid sleep, and he remarks that it has the advantage over ergot of not disturbing the stomach. It is of little or no use to check the bleeding of incipient abortion, but in menorrhagia, puerperal hemostaxis, and the hemorrhages associated with the climacteric, especially the first and third of these forms of uterine hemostaxis, it is highly efficient. The dose in which he has prescribed the drug is three quarters of a grain, two or three times a day as a rule, but in some instances as many as five times in twenty-four hours. In no case does he appear to have observed any untoward effects.

In our issue for June 17th we gave a summary of Nassauer’s experience with stypicin in the treatment of uterine hemostaxis and dysmenorrhea, which seems to have been even more satisfactory than Abegg’s, but it appears that Nassauer used larger doses than those prescribed by Abegg, and dwelt more on the analgetic action of the drug. It is to be hoped that further observation will show that we have in stypicin a uterine hemostatic and sedative of no mean value.

GELATIN AND THE HEMORRHAGIC DIATHESIS.

The announcement, made not long ago, that gelatin was an efficient hemostatic, has been well supported by abundant subsequent observation. The efficacy of the agent in arresting various forms of hemorrhage seems to be established, and it is satisfactory to observe that the hemostatic diathesis does not wholly rob it of its power to arrest bleeding, as has been observed by a number of French physicians. An interesting case exemplifying this fact has been recorded by Dr. R. Heymann, of Leipzig ("Münchener medizinische Wochenschrift," August 22d; "Indépendance médicale," September 13th). A young man complained of frequent attacks of epistaxis. On either side of the nasal septum, about a third of an inch back from the nostril, there was an area of little dilated vessels which bled on being touched gently with a probe. There was chronic nasal catarrh, and there were adenoid vegetations in the pharynx. After the removal of the adenoids there was such persistent hemostasis as to give rise to anxiety. All the ordinary means of checking it were employed without success, but the injection of a sterilized solution of gelatin had the desired effect.

THE PREVENTION OF THE ABUSE OF MEDICAL CHARTER.

The new rule established by the State board of charities requiring the dispensaries to inquire as to the ability of applicants for free treatment to pay for medical services, and to deny such treatment to those whom they find unworthy, bids fair to be found difficult of execution unless its terms are somewhat modified. In particular, it seems to be considered burdensome to the dispensaries that the cost of the necessary investigation should fall upon them, and it has been proposed that, since the State insists upon the inquiry, the expense should be met by an appropriation of State funds. This, however, is a matter which probably can and will be adjusted equitably when time enough has elapsed to show what extent, if at all, the State board’s requirement is necessary.

CARDIAC WEAKNESS AS A CAUSE OF GANGRENE.

Even in young children weakness of the heart’s action is to be reckoned with as an occasional cause of gangrene. A striking case in point is reported by Dr. Zuippinger, of Vienna ("Wiener klinische Wochenschrift," 1899, No. 13; "Prager medizinische Wochenschrift," November 2d). It was that of a girl, five years old, in whom gangrene of the skin of the back, of one foot, and of the great toe of the other foot occurred during the stage of resolution of a cranium pneumonia. There was considerable loss of tissue, but the child recovered.

WOMEN AS SURGEONS.

From the Journal of the American Medical Association for November 8th we learn that "In Australia the argument advanced by the opponents of the measure to appoint women physicians to the hospitals was that at certain physiological periods women are a source of danger to" (patients suffering from) "surgical diseases." We presume that in hospitals where such views obtain only male nurses are employed.

THE HOSPITAL SHIP MAINE.

The earnestness of the Americans who are fitting out a hospital ship for the benefit of their British kinsmen in southern Africa has been abundantly attested. Recent information is to the effect that the handsome sum of twenty-five thousand dollars has been received as the contribution of a single individual. As we have before remarked, we consider the undertaking most laudable.

SUGAR AS A SUSTAINING AGENT.

Sugar has long been credited with some efficiency as a strengthener of uterine contractions, and now a German experimenter, according to a dispatch to the Sun, finds it a prompt restorative in cases of fatigue due to muscular exertion. Three or four lumps are said to answer the purpose.

EUROPEAN CO-OPERATION IN THE SANITARY PROTECTION OF THE UNITED STATES.

It goes without saying that every civilized country may be relied upon to take ordinary measures to prevent the spread of infectious diseases, not only within its own confines, but beyond them. Nevertheless, the thoroughness with which various European countries are working to guard against the emigration of persons likely to carry with them the danger of infection, as shown by the recent observation of the health officer of the port of New York, is most gratifying.

ACTING ASSISTANT SURGEONS IN THE ARMY.

We learn that on Tuesday of next week there is to be held in the Seventh Regiment armory a meeting of the gentlemen who served as acting assistant surgeons in the army during the Spanish-American War,
for the consideration and adoption of measures to secure by congressional action the status to which such surgeons think themselves entitled. We earnestly hope the movement will prove successful, and that any concession obtained may apply also to those who have served in the capacity of contract surgeons in the army at any time.

**ITEMS.**

### Infectious Diseases in New York

We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported for the two weeks ending November 25, 1899:

<table>

**Dengue in the Philippines**—Chief-Surgeon Woodruff reports from Manila that a severe epidemic of dengue is prevailing on the island of Luzon.

**The St. Louis Medical Society**—At the last regular meeting on Saturday evening, November 25th, Dr. J. B. Ross reported the following cases: Adeno-cystoma hepatis, with operation and recovery, and polyectye degeneration of both kidneys.

**The Buffalo Academy of Medicine**—At the last regular meeting, on Tuesday evening, November 28th, the following papers were presented for discussion: Lessons from Practice in Obstetrics, by Dr. P. W. Van Puyama; and Mensuration and Capacity of the Female Bladder, by Dr. Lyon.

**The Chicago Society of Internal Medicine**—At a joint meeting of this society and the Chicago Medical Society, on Wednesday evening, November 29th, Dr. J. G. Adami, of Montreal, delivered the annual lecture on Latent Infection and Sub-infection, with Special Reference to the Etiology of Pernicious Anemia.

**The German Medical Society of the City of New York**—The annual meeting will be held on Monday evening, December 4th. Patients and specimens will be shown, Dr. F. Schwartz will read a paper on Syphilis and Arteriosclerotic Aortitis and the Formation of Aneurysm, and Dr. A. Meyer will read one on State Care of Indigent Consumptives, with a Description of the Massachusetts State Hospital for Tuberculosis.

**The International Otolological Congress**—We learn that, owing to the date for holding the International Medical Congress falling in 1903, it has been decided that the next International Otolological Congress shall not take place in that year, but in 1902. The meeting will be held in Bordeaux, under the presidency of Dr. Masure.

**Changes of Address**—Dr. Frederick A. Eggersman, to No. 166 East Ninetieth Street, New York; Dr. David Friedman, to No. 197 Lenox Avenue, New York; Dr. Louis J. Ladenka, to No. 1289 Madison Avenue, New York; Dr. Belle J. Macaloon, to No. 512 Fifth Avenue, New York; Dr. David M. Marvin, to No. 12 West One Hundred and Thirty-second Street, New York; Dr. G. R. Pisick, to No. 230 East Seventy-second Street, New York.

**Marine-Hospital Service Health Reports**—The following cases of small-pox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending November 24, 1899:

| **Small-pox—United States.** | 
|-------------------------------|---|
| Chicago, Ill. | Nov. 18 | 2 cases |
| Louisville, Ky. | Nov. 19 | 1 case |
| New Orleans, La. | Nov. 19 | 1 case |
| Chippewa, Mass. | Nov. 20 | 3 cases |
| Cleveland, Ohio | Nov. 21 | 1 case |
| Portland, Me. | Nov. 22 | 3 death. |
| Seattle, Wash. | Oct. 17-24 | 5 cases |

| **Small-pox—Foreign.** | 
|------------------------|---|
| Antwerp, Belgium | Oct. 21-29 | 5 cases |
| Prague, Bohemia, Austria | Oct. 21-28 | 9 cases |
| Bradford, England | Oct. 22-Nov. 4 | 1 case |
| Gibraltar | Oct. 22-Nov. 4 | 2 cases |
| Athens, Greece | Oct. 22-Nov. 4 | 7 cases |
| Bombay, India | Oct. 1-24 | 9 cases |
| Madras, India | Oct. 24-30 | 1 death |
| Messina, Italy | Oct. 28-Nov. 4 | 1 case |
| Osaka and Hiogo, Japan | Oct. 1-14 | 1 case |
| Shanghai, China | Nov. 4-11 | 11 cases |
| Vera Cruz, Mexico | Nov. 2-9 | 7 cases |
| Odessa, Russia | Oct. 29-Nov. 4 | 2 cases |
| St. Petersburg, Russia | Oct. 2-Nov. 4 | 7 cases |
| Warsaw, Russia | Oct. 16-22 | 5 cases |
| Straits Settlements, Singapore | Oct. 23-Nov. 4 | 7 cases |
| Constantinople, Turkey | Oct. 31-Nov. 6 | 1 case |

| **Yellow Fever—United States.** | 
|-------------------------------|---|
| Key West, Fla. | Nov. 12-20 | 2 cases |
| Miami, Fla. | Nov. 15-22 | 25 cases |
| New Orleans, La. | Nov. 18-26 | 2 cases |

| **Yellow Fever—Foreign.** | 
|---------------------------|---|
| Bahia, Brazil | Oct. 12-23 | 1 case, 1 death |
| Barranquilla, Colombia | Oct. 22-28 | 1 case, 1 death |
| Havana, Cuba | Nov. 4-11 | 5 cases |
| Nuevitas, Cuba | Nov. 14 | 1 death |
| Vera Cruz, Mexico | Nov. 15-21 | 4 cases, 3 deaths |

| **Cholera.** | 
|-------------|---|
| Bombay, India | Oct. 17-24 | 1 death |
| Osaka and Hiogo, Japan | Oct. 7-14 | 1 case |

| **Plague—United States.** | 
|------------------------|---|
| New York Quarantine | Nov. 18 | 1 suspected death on British S. S. J. W. Taylor, from Santos, at sea; 2 suspected cases on board |

| **Plague—Foreign.** | 
|-----------------|---|
| Santos, Brazil | Oct. 22-Nov. 17 | 2 cases, 10 deaths |
| Sao Paulo, Brazil | Oct. 17-Nov. 17 | 2 cases |
| Plymouth, England | Oct. 9 | 1 case on S. S. Penitentiary from Bombay |
| Bombay, India | Oct. 10-24 | 128 deaths |

**St. Mark's Hospital**—On Saturday night, November 25th, a concert in aid of the hospital was given at the Metropolitan Opera House. We are glad to learn that the proceeds were considerable.

**Army Intelligence**—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 18 to November 25, 1899:

**Banister, William B., Captain and Assistant Surgeon, United States Army, having reported, will proceed by the transport Logus to Manila, and, on arrival, will report for assignment to duty.**
Cooney, Daniel C., Acting Assistant Surgeon, United States Army, will report at Hamilton Barracks, New York, for duty with the troops while on practice marches.

Greenleaf, Charles T., Colonel and Assistant Surgeon-General, United States Army, will proceed to the Philippine Islands on the United States transport Hancock.

Maas, Louis M., Major and Surgeon, United States Army, is assigned to duty with troops on the United States transport Hancock, during the voyage of that vessel to the Philippine Islands.

O’Reilly, Robert M., Major and Surgeon, United States Army, will proceed to Fort Monroe, Virginia, to relieve De Witt, Calvin, Lieutenant-Colonel and Deputy Surgeon-General, United States Army, who will proceed to New York city for duty.

Wells, G. M., Captain and Assistant Surgeon, United States Army, will temporarily assume the duties of attending surgeon at these headquarters during the absence of Reynolds, F. P., Captain and Assistant Surgeon.

Wood, O. W., Acting Assistant Surgeon, United States Army, will proceed to Seattle, Washington, and report on the transport Victoria, for duty during the voyage of that vessel to the Philippine Islands.

Wooson, Robert S., Captain and Assistant Surgeon, United States Army, will report for temporary duty at the United States General Hospital, Presidio of San Francisco, awaiting transportation to the Philippine Islands.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending November 25, 1889:

Heneberger, L. C., Surgeon. Ordered to temporary duty, November 23d, in connection with the recruiting rendezvous, Detroit, Michigan.

Harris, H. N. T., Passed Assistant Surgeon. Ordered to New York, December 4th, for examination for promotion, and then home and to wait orders.

Simons, M. H., Medical Inspector. Ordered to the naval recruiting rendezvous, 177 Main Street, Buffalo, New York.

Price, A. F., Medical Inspector. Ordered to be examined for promotion at Washington, D. C., November 29th, and then to wait orders.

Lemson, G. P., Surgeon. Detached from the naval recruiting rendezvous, Buffalo, New York, and ordered home to wait orders.

Dickinson, D., Medical Inspector. Detached from the naval hospital, Washington, December 1st, and ordered home to wait orders.

Hancock, F. B., Assistant Surgeon. Resignation accepted, to take effect from November 25th.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending November 23, 1889:

Carter, H. R., Surgeon. To report at Washington, D. C., for special temporary duty.

Carmichael, D. A., Surgeon. Leave of absence for thirty days granted by Bureau letter of August 23, 1899, revoked.

Magruder, G. M., Surgeon. Referred from duty at Memphis, Tennessee, and directed to report at Washington, D. C., for special temporary duty.

Gehring, F. H., Passed Assistant Surgeon. To proceed to New York, for special temporary duty.

Smith, A. C., Passed Assistant Surgeon. To report at Washington, D. C., for special temporary duty. To rejoin station at Norfolk, Virginia. November 22, 1899.

Grubbs, S. B., Assistant Surgeon. Referred from duty at Cienfuegos, Cuba, and directed to report at Washington, D. C., for special temporary duty.

Robinson, D. E., Assistant Surgeon. Referred from duty at Mobile, Alabama, and directed to proceed to Memphis, Tennessee, and assume command of the service.

Thomson, F. J., Assistant Surgeon. Referred from duty at New York (Immigration Depot), and directed to proceed to San Francisco, California, for duty and assignment to quarters.

Bready, J. E., Acting Assistant Surgeon. Granted leave of absence for seven days.

Clarke, F. M. Acting Assistant Surgeon. Granted leave of absence for ten days from November 20th.

Dudley, D. E., Acting Assistant Surgeon. Department letter of October 31, 1899, granting Acting Assistant Surgeon Dudley leave of absence from November 1, 1899, amended so that said leave shall date from November 16th.

Smith, F. R., Acting Assistant Surgeon. Granted leave of absence for four days.

Achenbach, John, Hospital Steward. Referred from duty at Port Townsend, Washington, and directed to report to the Port Townsend Quarantine station, Washington, for duty.

Brook, G. H., Hospital Steward. Referred from duty at New Orleans, Louisiana, and directed to proceed to Cincinnati, Ohio, for duty and assignment to quarters.

McKay, M., Hospital Steward. Referred from duty at Boston, Massachusetts, and directed to proceed to New York (Stapleton), for duty and assignment to quarters.

Allen, G. C., Hospital Steward. Referred from duty at New York (Stapleton), and directed to proceed to the Delaware Breakwater Quarantine station for duty and assignment to quarters.

Peck, F. H., Hospital Steward. Referred from duty at Baltimore, Maryland, and directed to proceed to New Orleans, Louisiana, for duty and assignment to quarters.

Olson, E. T., Hospital Steward. To rejoin station at Wilmington, North Carolina.

Troxler, R. F., Hospital Steward. Referred from duty at San Francisco, California, and directed to proceed to Port Townsend, Washington, for duty and assignment to quarters.

Society Meetings for the Coming Week:

Monday, December 4th: New York Academy of Sciences (Section in Biology): German Medical Society of the City of New York; Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Corning, New York, Academy of Medicine; Utica, New York, Medical Library Association; Boston Society for Medical Observation; St. Alans, Vermont, Medical Association; Providence, Rhode Island, Medical
Association; Hartford, Connecticut, Medical Society; South Pittsburgh, Pennsylvania, Medical Society: Chicago Medical Society.

Tuesday, December 6th: Southern Surgical and Gynecological Association (first day, New Orleans); New York Neurological Society; Buffalo Academy of Medicine (Section in Surgery); Elmira, New York, Academy of Medicine; Ogdensburgh, New York, Medical Association; Syracuse, New York, Academy of Medicine; Medical Societies of the Counties of Herkimer (seminannual) and Saratoga (seminannual, Ballston Spa); Hudson, New Jersey, County Medical Society (Jersey City); Androscoggin, Maine, County Medical Association (Lewiston); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

Wednesday, December 7th: Southern Surgical and Gynecological Association (second day); New York Academy of Medicine (Section in Public Health); Society of Alumni of Bellevue Hospital; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond, New York (New Brighton); Penobscot, Maine, County Medical Society (Bangor); Bridgeport, Connecticut, Medical Association.

Thursday, December 7th: Southern Surgical and Gynecological Association (third day); New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, New York; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington); Medical Society of City Hospital Alumni, St. Louis; Atlanta Society of Medicine.

Friday, December 8th: Yorkville Medical Association, New York (private); Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, New York.

Saturday, December 9th: Obstetrical Society of Boston (private).

**Births, Marriages, and Deaths.**

**Married.**

ALGER—STEVENS.—In Bradford, Pennsylvania, on Tuesday, November 21st, Dr. Ellice M. Alger, of New York, and Miss Louise Stevenson.

BRADY—BRASIER.—In Brooklyn, on Wednesday, November 22d, Dr. William Joseph Brady, of New York, and Miss Isabel Brasier.

BUCK—BADGER.—In Marion, South Carolina, on Wednesday, November 22d, Mr. Henry Buck and Miss Lula Badger, daughter of Dr. Benjamin M. Badger.

CODMAN—BOWDITCH.—In Jamaica Plain, Massachusetts, on Thursday, November 16th, Dr. Ernest Amory Codman and Miss Katharine Putnam Bowditch.

GOODE—CABANNE.—In St. Louis, on Wednesday, November 22d, Captain George W. Goode and Miss Susie C. Cabanne, daughter of Dr. James S. Cabanne.

ORMISTON—HAZEN.—In Brooklyn, on Wednesday, November 22d, Mr. Henry Theodore Ormiston, son of Dr. Robert Ormiston, and Miss Florence Leyard Hazen.

**DEATHS.**

TENNANT—BAYNE.—In Washington, on Wednesday, November 22d, Mr. David Bullington Tennant and Miss Mae Ashby Bayne, daughter of Dr. John W. Bayne.

Died.

BALDWIN.—In Brooklyn, on Sunday, November 26th, Jeanette Newton Baldwin, infant daughter of Dr. L. Grant Baldwin.

CARROLL.—In Washington, on Sunday, November 5th, Dr. J. J. Carroll, United States Army.

MARTIN.—In Madison, New Jersey, on Friday, November 24th, James Lee Martin, son of Dr. W. Hammet Martin.

GREENE.—In Richburg, New York, on Monday, November 27th, Dr. Sheffield W. Greene, in the eighty-fifth year of his age.

WILLIAMS.—In Colorado Springs, on Wednesday, November 22d, Dr. Frederick W. Williams, of New York, in the fortieth year of his age.

**Special Articles.**

**The Law in Its Relations to Physicians.**

By ARTHUR N. TAYLOR, LL.B.

XLVII.

**Privileged Communications.**

(Continued from page 791.)

Knowledge Coming within the Law.—The question of what knowledge is within the meaning of these statutes is often a very nice one, and it is a question upon which the courts have many times been unable to agree.

There is no doubt, however, that the statute does not preclude one from stating that he is the family physician of another, nor from giving the number and dates of his professional visits, and the date upon which he discharged the patient. The disclosures which the law aims to preclude the physician from making are those facts which he learns in the course of his professional employment, and to construe the statutes so as to give them this effect is the apparent design of the courts.

The statute of New York provides that one practising medicine and surgery shall not be permitted to disclose “any information which he acquired in attending a patient in a professional capacity.” With the exception of five States to be hereafter referred to, each of the States having statutes upon this subject has almost literally reenacted that part of the New York statute included within the quotation, which describes the knowledge that is protected.

It seems well settled that this clause in the statutes

‡ Kelley vs. Highfield, 15 Or., 277.
§ The five States not following the wording of the New York statute in the above particular are Indiana, Iowa, Nebraska, Ohio, and Wyoming.
includes all knowledge gained in the professional intercourse of a physician with his patient, whether obtained from statements made to him by the patient or gained from observing and examining the patient. A leading case upon this subject is that of Edington vs. Mutual Life Insurance Company. In this case Justice Miller says: "When it (the statute) speaks of information, it means not only communications received from the lips of the patient, but such knowledge as may be acquired from the patient himself, from the statements of others who may surround him at the time, or from observation of his appearance and symptoms. Even if the patient could not speak, or his mental powers were so affected that he could not accurately state the nature of his disease, the astute medical observer would readily comprehend his condition. Information thus acquired is clearly within the scope and meaning of the statute." The law, as stated by the learned judge in this case, has been cited with approval and followed in a number of succeeding cases in New York and elsewhere. The examination of the patient referred to in these cases covers not only the thorough and careful examination made for the purpose of prescribing, but includes as well impressions or opinions regarding the patient's condition formed from his general appearance as disclosed at first sight, before the physician has had an opportunity to examine or converse with him. Nor will the seal of silence be removed from the doctor's lips because the examination may have been conducted in the presence of others.

In the States of Indiana, Iowa, Nebraska, Ohio, and Wyoming the statute provides that physicians shall not be allowed to disclose matter "communicated" to them by their patients, or to disclose any "communication," etc. The wording of this statute would seem at first sight to restrict the protection of privilege to such information as the physician received by communications from the lips of his patients; yet, however, does not seem to be the understanding of the courts which have passed upon the question. The supreme court of Indiana, after quoting the statute of that State, says: "It sets the seal of secrecy and confidence upon what a physician observes in respect to the condition of his patient's person in the course of his professional examinations, as well as upon communications made to him by his patient. Accident or disease may compel the submission of one's person to examination by a physician, who thus acquires information which would be confided to no one else. The fear of disclosure often induces persons to suffer from bodily ailments rather than submit to examination by persons of skill. The policy of the statute is to protect and render inviolable the confidence which should exist between physician and patient. A physician is not permitted to disclose the result of observations or examinations made by him upon the person of his patient, unless with the consent of the latter, or unless the patient in some way waives his privilege." [1] And in a late case the supreme court of Iowa says: "Although the statute of this State uses the word 'communication' it means much the same as the word 'information' in the statutes of other States to which we have referred. The prohibition of our statute refers not merely to verbal communications, but to those of any kind by which information of the character of that specified in the statute is imparted." The courts of last resort in the other three States having statutes similarly worded have not yet passed upon this particular question. It is hoped, however, that when a case involving this point shall be placed before them, they will be able to reach the same conclusion as that arrived at by the courts of the two sister States, for such a construction of the statute is more in accord with the true professional spirit of reserve regarding matters necessarily and confidentially disclosed to enable the physician to properly perform the functions of his profession.

By the statute of nearly every State the protection of the law is restricted to the knowledge gained by the physician which was "necessary and proper to enable him to discharge the functions of his office." The wording of the statutes of several of the States is different, yet the meaning conveyed is quite the same. In construing this clause of the statute there has been a lack of harmony, the courts at one time having shown a disposition to place a strict construction upon the statute and exclude all matter from the protection of the privilege which was not essential or necessary for diagnosticating or prescribing for the ailment; while the courts at a subsequent and previous period as well have shown a disposition to give the statute a more liberal construction, and include within its protection all communications which might reasonably or even remotely relate to the subject of the professional services.

There are certain communications that are manifestly outside of the protection of the law. Thus, where an unmarried woman told the physician who attended her at her confinement that the father of her child had never promised to marry her, the communication could not be withheld as privileged, for the statement was neither designed nor calculated to throw any light upon the patient's condition nor aid the physician in the remotest degree in his professional treatment of her. The courts have, however, in many cases shown a disposition to admit every doubt in behalf of a liberal construction of the statute. Thus, the evidence of a physician that he had treated a certain patient for venereal disease and that the patient told him he had contracted the disease from the cook on his canal boat, was excluded as coming within the statute. In this case the nature of the patient's affliction and the length of time he had been suffering from it are clearly within the protection of the statute, but there is room for doubt that the statement by the patient that he had had intercourse with his cook could have been intended or in any way designed to assist the doctor in the professional treatment of the case.

Probably the case most cited in favor of a strict construction of the statute is that of Edington vs. Elta Life Insurance Company. [2] Herein Justice Earl says: "It will not do to extend the rule of exclusion so far as

to embarrass the administration of justice. It is not even all information which comes within the letter of the statute which is to be excluded. . . Suppose a patient has a fever or a fractured leg or skull, or is a raving maniac. All these ailments are obvious to all about him. 'May not the physician who is called to attend him testify to these matters?' In doing so there would be no breach of confidence, and the policy of the statute would not be invaded. These and other cases which might be supposed, while perhaps within the letter of the statute, would not be within the reason thereof.' Justice Earl gives it as his opinion in this case that the party attempting to avail himself of the privilege of the statute must show that the information acquired by the physician was 'such as was necessary to enable him to prescribe or to do some act as a surgeon.' In harmony with the spirit of this decision is the case of Campan vs. North, wherein a physician was permitted to testify to the date upon which a patient had told him she received a breach, for which he was treating her professionally. The court thought that the time the patient received the rupture, or rather the existence of the rupture, prior to a certain date, was not information "necessary to enable the doctor to prescribe for her as a physician or to do any act for her as a surgeon." The case of Linz vs. Massachusetts Mutual Life Insurance Company † presents the views of a court favoring a strict construction of the statute. Justice Hayden, in this case, after quoting with approval from the opinion of Justice Earl in the Edington case, says: "Objective signs that are obvious, or such an observation as implies no disclosure—symptoms which are apparent before the patient submits himself to any examination—the statute gives no authority for excluding. That a patient had an inflamed face, a bloodshot eye; that fumes of alcohol proceeded from his person; that he talked deliriously, could be excluded only on the basis that the statute forbids a physician to be a witness. These objective signs, and others which imply no knowledge obtained as the result of submission or exposure by the patient, and which would be apparent before the initial act of service on the physician's part, the latter should testify to under our statute." These three cases present the extreme view favoring a strict construction of the statute. This view has not been approved or followed by later cases, and it is very much doubted whether it may be considered the law. The case of Kling vs. The City of Kansas ‡ probably presents the true doctrine. In this case the question was presented to the court whether or not a physician should be permitted to disclose the condition of a patient with regard to sobriety at the time of calling upon him to render professional services. The court, in an elaborate and learned opinion, explains clearly and satisfactorily the meaning of the statute with reference to the question of what information is "necessary information." The court is of the opinion that all information, although unimportant in itself, which is necessarily communicated to the physician in order to give him the knowledge needed to act in a proper professional capacity is "necessary information." It is evident that the information necessarily imparted to a physician to give him a clear understanding of all the

† Raymond vs. B. C. R. and N. Ry. Co., 65 In, 152.
Pith of Current Literature.

The Treatment of Typhoid Fever.—Dr. Reginald H. Fitz, of Boston (Boston Medical and Surgical Journal, November 23d), says that the conclusions reached from a study of the records of the Massachusetts General Hospital for the past seventy-eight years on typhoid fever with regard to mortality, intestinal hemorrhage, perforation, and relapse are as follows: 1. The treatment of typhoid fever does not differ in essentials from the principles laid down in 1839. 2. The average mortality from this disease has not materially changed from the days of active treatment with emetics, purgatives, venesection, antimony, and calomel down to the present time. 3. Intestinal hemorrhage, perforation, and relapse, upon the whole, are quite as frequent now as at any period in the history of the disease. 4. A considerable variety in diet may be permitted not only without detriment, but also with possible benefit to the patient.

The Treatment of Goitre.—Dr. Albert J. Bouffleur (Medicine, November) says that from our present knowledge of goitre the following general conclusions seem justifiable: 1. Successful treatment depends upon accurate and early diagnosis of the nature of the goitre. 2. Struma should be treated by the internal use of iodine or thyroid extract and the intraperinechymatous injection of iodiform or carbolic acid. 3. If these fail, either enucleation or partial thyreoidectomy is indicated. 4. Adenoma should be treated by enucleation if the tumor is small, and by partial thyreoidectomy if of large size. 5. Cysts should be treated by evacuation and injection of carbolic-acid solution or iodiform emulsion. 6. If this fails, they should be enucleated. 7. Sarcoma and carcinoma should be treated by complete removal of the thyroid gland, with subsequent administration of thyroïd extract. 8. The treatment of exophthalmic goitre is generally unsatisfactory, and at the present time surgical measures promise the best results. 9. Undifferentiated goitre may be treated by thyroid extract and iodine, but intraperinechymatous

* The Penn. Co. vs. Marion, 123 Ind., 415.
† Louisville, etc., R. R. Co. vs. Berry, 9 Ind. App., 63; Citizens' Street R. R. Co. vs. Stoddard, 10 Ind. App., 278.
* Kelly vs. Levy, 8 N. Y. Supp., 849.
injections, and if necessary operative treatment, should be employed early. 10. The surgical treatment of all varieties of chronic gout is, generally speaking, the most successful and most satisfactory.

The Treatment of Syphilis.—Mr. A. H. Ward, surgeon to the London Lock Hospital (British Medical Journal, October 21st), thus sums up his conclusions in a paper read before the British Medical Association: "Mercury should be used alone in primary and secondary syphilis, unless severe lesions are present. Treatment should be begun at the earliest possible moment. The drug should be given in a form easy to take, and not irritating to the stomach. It should be carefully pushed to the toleration point indicated by slight touching of the healthy gums. When the toleration point is reached, the mercury should be kept up to that point throughout the course; never higher, lest the patient be poisoned; never lower, lest sporing instead of destruction of the microbes occur. The course should continue for two years, that being the period of natural cure or real latency. Iodides should not be used as routine treatment in the primary and secondary stages, because, by removing the toxine, the phagocytes will be no longer attracted to the microbes, and encapsulation and destruction will be hindered. Iodides together with mercury, to be used in increasing doses in the gummatus stage; later a mild mercurial course is advisable. In intractable cases, with chronic blood poisoning and severe lesions, a large quantity of water taken daily facilitates the excretion of the toxine, and in the shape of Zittmann's decoction is undoubtedly very effectual. Finally, it is my conviction that the point of central importance in the treatment of syphilis is to push the mercury to the toleration point, and to keep it there throughout the case. This is the final sum of my experience."

The Infectivity of Malignant Growths.—Mr. Bellingham Smith and Dr. Washbourn (Lancet, October 28th) recently communicated to the Medical Society of London a paper on this subject as a result of theoretical, clinical, and experimental researches. The authors sum up their conclusions as follows: 1. A malignant growth might be regarded as local in origin and as possessing the power of infecting adjacent and distant parts of the same individual. 2. Inoculation might take place from one point to another of the same individual apart from transference by the natural channels. 3. There was good evidence to show that one individual might be infected with growth from another. 4. There was experimental evidence to show that growths might be transferred from animal to animal of the same species by inoculation. 5. There were found in many malignant growths bodies which had a resemblance to microorganisms and which had been regarded as belonging either to the protozoa or the blastomyecetes. 6. A new growth having the structure and also the behavior of carcinoma had been described as occurring, at any rate, in two instances from inoculation with a form of blastomyeces. 7. These experiments were highly suggestive that the bodies found in cancer were the cause of the disease, though the evidence was wanting that directly associated the two.

The Treatment of Ringworm.—According to the London correspondent of the Medical News for November 11th, a most ingenious little appliance for the treatment of obstinate cases of ringworm was recently displayed by Dr. Phineas Abraham in a clinical demonstration at the London Polyclinic. It was born of the recognition of the fact that in chronic cases of great persistence, such as we have all had painful experience of, the principal stronghold of the tinea is not in the skin of the scalp, but deep in the follicles of the hair, into which, of course, ordinary ointments rubbed or solutions painted upon the surface of the skin could hardly by any means be got to penetrate. Its principle was suggested to Dr. Abraham by the process by which blocks for wood paving are saturated with creosote in vacuo. These are placed in a retort from which the air is rapidly exhausted by an air pump, and then creosote in the form of vapor is introduced, and as the result of the "vacuum" having penetrated some distance down the tubes and fibres of the wood the vapor is literally sucked or drawn completely through and through the mass. This process is imitated in a lesser degree upon the scalp by a small bell jar with a rubber rim, which, after the scalp has been thoroughly cleansed with alcohol and ether, is pressed upon the area desired to be treated and the air within rapidly exhausted by a small syringe pump. When the tissues have been well sucked up into the cavity of the cup a cock in the bottom of a small tube of creosote is opened and the drug, in the form of vapor, pours into the vacuolated tissues. Dr. Abraham has found it of great practical value in sterilizing not merely the surface, but even the depths of the hair follicles, and by this means alone has succeeded in curing many obstinate cases which had defied all other methods of treatment.

Conservative Surgery on an Arm completely Crushed by a Locomotive.—The following case, showing how by patience a serviceable limb may sometimes be saved in almost hopeless cases, is reported by Dr. S. L. Kilmer in the Virginia Medical Semi-Monthly for October 13th:

About three o'clock in the morning of October 26, 1897, he was called to attend a yard switchman in the employ of the Lake Shore and Michigan Southern Railway, at South Bend, Indiana. In turning to step from the foot-board of the engine, the man had slipped and fallen in front of the engine, which at that moment started. The engine, in running over him, had dragged him for some distance. Perhaps he caught hold of some part of the engine to protect himself, but in any event he was dragged over the ties for some thirty or forty feet. His left arm lay across the rail, and one or more wheels of the engine ran squarely over it, crushing the bones into short lengths and fragments, and mangle and crushing the soft tissues in the usually frightful manner in such cases. There was also a scalp wound of some four inches in length, extending to the skull.

After a primary examination, the patient was removed to the Epworth Hospital, where a more careful examination of the arm was made, and the foregoing description was found to be not in the least exaggerated. Dr. Kilmer's first impulse was to amputate the arm above the elbow, as being the proper course to pursue in consequence of the terribly mangled condition of the entire forearm. However, he remembered having read, not long previously, the results of a German surgeon who had for some time made a specialty of endeavoring to avoid amputation in all cases where it was possible to do so, leaving, practically speaking, amputations to Nature, under the opinion that Nature was more conservative than art as practised by the surgeon, and
a better judge of the actual requirements than he. His method was simply to assist Nature when it was evident that she was performing an amputation; and thus to ascertain whether it were not possible to save many cases which, under the usual practice, had been sacrificed. His success had been so marvellous as to even astonish himself—saving many limbs that appeared hopeless, and a generous portion of the limb of many others—to the great benefit of the patient.

The author was the more easily inclined to believe that it would be perhaps justifiable to make the effort in this case to save the arm, despite its almost hopeless outlook, inasmuch as the arteries had fortunately escaped severing, as indicated by their continued pulsation—although it was feared their injury might cause them to slough, and thus bring on secondary hemorrhage.

The decision being made, Dr. Kilmer enlarged one of the openings, from which protruded bones and mangled flesh, sufficiently to enable him to examine carefully with the fingers the entire interior. He removed with scissors a large amount of comminuted soft tissue; one section of the radius, two inches and three quarters in length, which was entirely free from the soft tissues, was also removed, together with a number of fragments of bone of various sizes. A portion of the ulna, two inches and a quarter in length, being still attached to some of the soft tissues, was permitted to remain, with the hope that it might perhaps receive a sufficient amount of nourishment to protect its vitality.

After having thoroughly irrigated the vast cavity within the forearm, and trimmed off as much as possible everything that was beyond the possibility of reparative process, drainage was provided for, and the fragments of bone were replaced in as natural a position as possible. The arm was extended and laid upon a straight posterior board splint, extending from the axilla beyond the finger tips, carefully packed in a gauze dressing, and light bandages were applied. Strict asepsis was of course out of the question in this case, but the general principles of antiseptic treatment were complied with as closely as possible under the circumstances.

The next day there was, as was to be expected, a great deal of tumefaction, the swelling extending well up to the axilla; the skin over the forearm, and extending some distance above the elbow, was much discolorcd, almost black; while the temperature was 101° F. On the following day the conditions were worse, and Dr. Kilmer began to fear that a great error had been made in the attempt to save the arm. However, the condition remained, practically speaking, stationary for several days, and then began a profuse purulent discharge.

There were formations of pus at various places between the elbow and wrist; in fact, there was a generally suppurring condition of the entire forearm, necessitating the free use of the lance, so that the whole forearm resembled a sieve or bag, and upon irrigating with some little force, the fluid would discharge from half a dozen different openings.

After a few weeks a splint was constructed, composed of longitudinal iron bars, so curved as to allow free access to the openings in the forearm, and at the ends of the bars leather straps and buckles, by which the splint was held in position; the bones were again arranged as correctly as possible, and free drainage provided for. The limb could thus be handled and dressed without the removal of the splint. The discharge was very free for a period of probably two months, necessitating a change of dressing twice a day. Eventually, however, the swelling subsided greatly, the discharge diminished, and the general appearance of the arm improved. About this time he left the hospital for his home, coming to the doctor's office every day or two for treatment for several months longer. There was still considerable discharge, and it was evident there was some necrosed bone remaining. On the 9th day of May, 1898, an opening was made on the anterior or palmar surface of the forearm near the wrist, and the portion of the entire diameter of the shaft of the ulna, two inches and a quarter in length, referred to above as being left in the hope that it would survive, was easily removed, being found lying in a cavity of its own, entirely freed from all other tissues, and dead.

The periosteum had unfortunately failed to produce new bone, as was hoped, and apparently the contraction of the muscles had crowded out of position the portion of necrosed ulna, approximating the extremities of the fragments of the bones, between which there was a ligamentous union only. The wound was closed and nearly healed. The result is satisfactory, as the arm is quite useful, the patient having considerable power of flexion of the thumb and all the fingers, which enables him to hold a book or other object in his hand very comfortably. The ligamentous union, although quite short, unfortunately still permits the hand to droop, so that the arm becomes decidedly curved. This can, however, be corrected by wearing a splint for a few days, which serves to correct the position of the bones, or did until some months since. There is, however, now a contraction of the muscles, a slipping of the extremities of the bones over each other, and a shortening of about three inches. The arm is entirely well at this time—that is to say, it is entirely healed and is painless. The ligamentous union and the natural weakness incident to the terrible injury to the soft tissues make it of course a very imperfect arm, but it is in a very much better condition, and much more serviceable than would have been any artificial arm that could have been put on the stump, had it been amputated.
tion which keeps up a decided irritation and thus leads to enlargement and regrowth of the tonsil. This is particularly so in the lower part of the tonsil near the base of the tongue, where small prolongations are not removed. These extra projections or lobes often remain behind in the ordinary operation with the guillotine. This is a most useful instrument, but often requires to be supplemented by the scissors, snare, or punch. The object should be to remove as much of the tonsil as possible, and the anterior pillar is not by any means the external limit of diseased tonsillar tissue. We can do much more thorough work and have fewer recurrences if we give up the idea that all that is necessary in amygdalotomy is to make one cut with the guillotine, with the anterior pillar as a guide. In adults, but not often in children, there is a marked development of the so-called tonsillar fold, which spreads over the lower part of the tonsil and conceals it. This may be mistaken for the anterior pillar and the part of the tonsil behind it escapes removal.

Dr. James E. Newcomb, of New York: I quite agree with Dr. Farlow has said, and Dr. Hopkins has done a wise thing in calling our attention to this subject. It seems to me that without this perfect technique which Dr. Farlow has described and demonstrated there is a certain amount of lymphoid tissue left at the bottom of the tonsil. I think that frequently among the dispensary class of patients, those coming from tenement houses and going back to the same bad, unhygienic environment and the same conditions which have originated the original disease, are very often apt to return with a recurrence of the tonsil after excision. I have had some cases in which I have done what I believed to be a thorough operation, satisfying myself by inspection of the case three or four weeks afterward that the tonsil had been completely removed, yet I have seen such patients reappear with enlarged tonsils. This recurrence is not so striking in the better class of patients.

I should like to ask Dr. Farlow if he ever uses the snare in cutting out these tonsillar fragments.

Dr. Farlow: I have removed many tonsils and fragments with the snare. In those cases I have sometimes been able to remove the tonsillar tissue so completely that there has been no possibility of recurrence. The cases have been examined subsequently and no tonsillar tissue has been left, the tonsil having been entirely enucleated.

Dr. G. V. Woollen, of Indianapolis: A tonsil can not recur if it has been thoroughly enucleated. That is a fact which I think we all must recognize. I had the temerity to say at the American Medical Association in 1887 that there was no such thing as a tonsil, physiologically or anatomically speaking; that it was a pathological product, pure and simple. I have yet to retract that assertion, and I always look upon a tonsil as I do upon a wart or papilloma, or any extraneous growth, not always needing removal. When I have a tonsil which demands removal, I try to do it thoroughly. I have seen, at home and abroad, indications that would lead to just such reports as we have here—namely, that so long as we have a part of the tonsil left we may have a proliferation of tissue, just as we had originally. I have discontinued the use of the word removal or the word excision, or any such words as applied to the tonsil. The enucleation of the tonsil can be done with the guillotine; not, however, with the guillotine furnished by the instrument makers. One of the most misleading things in this surgical appliance is the elevator of the fork attached to the amygdalotome. I have taken this off, I use the French amygdalotome. I have the patient hold the tongue depressor, as it is desirable to engage his attention as much as possible. I raise the tonsil with a volella, so as to determine what amount of tonsillar tissue I wish to remove and see where its attachments are, drawing it out from behind the pillars, through the ring of the guillotine previously adjusted, then by means of the guillotine I seize the tonsil and cut where I desire. It should be a most deliberate operation. Since adopting this procedure I have not had many cases of recurrence. After I have taken the tonsil out, I examine the lacunae with a probe to see whether they are perforated or not, and thereby I determine whether there is any tonsillar tissue left to give further trouble. I have been surprised how by this procedure I could enucleate the tonsil, simply taking it out of its bed and leaving the pillars intact. Some of the worst cases of peritonsillar abscesses that I have ever seen have arisen from small portions of tonsil left behind.

Dr. D. Braden Kyle, of Philadelphia: Whether we have to deal with the tonsil as a physiological or pathological structure it matters little. Where it is of a low grade gland structure, and in at least the majority of cases, I agree with Dr. Woollen that it is pathological, and I also believe that it is more of a benign growth—a hyperplasia. In some cases there is no doubt that the tonsil recurs after excision. I have a number of sections in my laboratory showing various pathological alterations in tonsillar tissue, and I find in the few in which recurrence has taken place that the tissue largely resembles that of an adenoma. I think in some cases this fact possibly explains why we have recurrence—we are dealing in such cases with a benign growth and not a simple tonsillar structure.

Dr. G. Hudson Mauken, of Philadelphia: In my experience the tendency for the tonsil to recur after operations has been rare, and in this respect my experience differs from that of Dr. Hopkins. The chief cause of recurrence, as has been said, must be a lack of thoroughness in its removal. The general surgeon amputates the tonsil and, as Dr. Farlow has said, part of it is left behind the pillars; thus the last condition is worse than the first, because it leaves room and an opportunity for secretions to gather and cause further trouble. I think that the reason why amygdalotomy is looked upon with such disfavor is that the operation is not properly done. I would remove the operculum or fold referred to by Dr. Farlow as well as the tonsil. If you dissect the tonsil out from behind the fold you will leave a cup-shaped pocket for the collection of secretions and particles of food, and this becomes a source of irritation and infection.

I have devised a set of instruments for dissecting the tonsil away from the anterior and posterior pillars prior to the operation for amygdalotomy. This is a very important thing, for it enables the operator to do a more thorough operation.

Dr. Hopkins (closing the discussion): My only object in presenting this paper before the association was to have the matter of recurrence of the tonsil after excision take its proper position. With one exception our text-books are silent on the subject, and current papers do not refer to it. Recurrence does occasionally take place, and I thought that what the members of the association might have to say on the subject would tend to give it proper recognition and an authoritative position.

(To be continued.)
Book Notices.

Although manuals, text-books, and treatises on both operative and descriptive surgery have appeared in quick succession for the past few years, it is worthy of comment that they have not been able to do more than keep pace with its rapid strides. Good, bad, and indifferent works have come to our notice; we have, however, seen nothing better and few quite so good as the volume before us. No single pen can produce a work on all branches of surgery with the same success as can be achieved by the divided efforts of writers whose subjects have been carefully selected to meet their special qualifications. The contributors are all men firmly established as leaders in the profession, and their signatures stand as a guarantee of their articles.

The editors have wisely divided the work into two volumes, with the arbitrary but convenient separation into general surgery, to which the first volume is devoted, and special surgery, which will appear later in volume ii. The opening chapters differ but slightly from those of standard works by other authors. The addition of a chapter on the surgical pathology of the blood, seldom seen in a general work, is to be commended, for in accident cases we are often assisted in distinguishing nervous shock from shock due to hemorrhage by a proper examination of the blood. Again, in the diagnosis between such conditions as "pus tube" and hematocoele, the blood count will often be found useful. The systematic examination of the blood will often materially assist us in determining the probability of the recurrence of malignant neoplasms after operations for their removal.

A few pages are devoted to minor and operative surgery, including the subjects of amputations, excisions of joints and bones, osteotomy, and plastic surgery. Of the section on minor surgery, the greater part of the text is devoted to the proper methods of bandaging and to the practical uses of local anesthesia, followed by a well-written chapter on surgical anesthesia, general and local. We note that no complicated ether inhaler is advocated, but the simplest is advised. The writer states that "from the earliest days of modern anesthesia, the most common method of administering ether has been upon a towel folded in the shape of a bowl and stiffened with paper placed between the two outer layers, which serves partially to confine the vapor. Every patient should take his anesthetic, whatever it may be, from a thoroughly clean and fresh inhaler, as no other is either safe or decent."

About two hundred pages are given to fractures and dislocations, covering the more important injuries; following we have chapters on the diseases of bones and joints, including orthopedic surgery, the surgery of the spine, peripheral nerves, heart and blood-vessels and the lymphatics, and cranial surgery.

For the sake of convenience, the subjects treated of in the first volume of this work have been divided in such a way as to present in order the regions of the upper extremity, the back of the neck, the shoulder, the trunk, the cranium, the scalp, and the face. The surface anatomy of the upper extremities commands our first attention. The importance of surface markings is forcibly called to our notice in a most lucid and attractive way, which at once forces us to realize the undoubted qualifications of the author for the great task set before him. All general anatomical features which could be of interest to the reader are carefully portrayed in a number of beautifully executed illustrations including drawings of the ulnar deflection, also comparative views of normal and dislocated shoulders, together with demonstrations of surface markings, indicating the position of joints and the structures lying beneath.

The lines of skin incisions for dissection differ somewhat from those adopted in most of our text-books, and, we think, to great advantage, leaving as they do a most perfect covering, thus better preserving the underlying structures for future work.

The author next devotes himself to the dissection of the parts, and expresses his ideas and knowledge in a clear and forcible style which makes the reading as attractive as the rather dry subject will allow. The articulations, with their protective bursa, have been given special attention. Here, as elsewhere in the treatise, we note a leaning in favor of the more practical side of anatomy, fractures and dislocations, with their etiology and pathological anatomy, occupying considerable space. The section concludes with a full consideration of amputations, resections, ligation of arteries and streets of nerves, with eighteen full-page illustrations showing the dissections necessary for the ligation of arteries and the exposure of nerves.

The consideration of the surgical anatomy of the back of the neck and trunk takes up the next section. The same general lines of the previous chapter are adopted. Of more than ordinary interest is the dissertation on the different forms of spinal curvature, including, as it does, two full-page drawings illustrating their characteristic deformities.

The illustrations have, for the most part, been taken from original dissections especially prepared for this work. Drawings, as a rule, are perhaps not quite so realistic as photographs of the actual dissection, but they are much more instructive; we therefore think the author has been wise in adopting them. The drawings are all carefully prepared, and the writer's tribute to the artist, in his preface, is well merited. The clearness and beauty could perhaps be slightly improved upon by the addition of a little color.

The author, as stated in his preface, has devoted the past twelve years to preparing the complete treatise, and if volume i is an index of those to follow, we consider the time spent insignificant as compared with
the long life which the book has before it. We have in this volume a work which certainly equals anything of the kind we have hitherto seen.

The author states in his preface that "medical progress is so rapid in our day that manuals have special value, in that they may be published in the shortest possible time, and thus place before the reader the most recent advances in medicine. Moreover, a brief epitome presents the subject to the busy practitioner and student in a form more readily accessible than is possible in a lengthy treatise."

Brevity undoubtedly a prominent feature of this work. Some of the subjects, we fear, have suffered, however, from their treatment being rather too much curtailed; in fact, some of the less common diseases have not been given more than sufficient space for a proper definition. The writer frequently refers to the standard authors of the day, and with their aid has succeeded in giving us the very latest information obtainable, all of which we can heartily indorse.

The chapters on the diseases of the stomach are especially commendable, but even here we find the concluding lines rather too abrupt, for the possible sequelae are dismissed with the remark "complications call for appropriate medical treatment," a well-recognized principle, which, however, leaves too much to be inferred.

This volume maintains the high standard of excellence established by the preceding volumes of the work. Possessing the same admirable qualities which have characterized them—uniformity of merit in the several contributions, critical appreciation of recent advances in medical knowledge, logical discussions of etiology, picturesque descriptions of symptoms, rational views of treatment—it compares favorably with the corresponding volumes of the numerous contemporaneous systems of medicine.

The first section of the book, a thorough and comprehensive treatise by Merklen on diseases of the heart, forms nearly one half of its bulk. The first two chapters describe in an unusually graphic and interesting manner the functional and physical signs of disease of the heart. The following chapters treat of the diseases of the pericardium, endocardium, coronary arteries (this title including coronary arteritis, angina pectoris, infarcts, rupture, and partial aneurysms of the heart), and myocardium. The best parts of these chapters are the descriptions of cardiac syncope, angina pectoris, and chronic myocarditis. Another noteworthy chapter, that on the complications of cardiac disease, contains an exceedingly instructive discussion of asystolie, the title, "etymologically incorrect, but consecrated by usage," given by the French school to the ensemble of symptoms resulting from cardiac insufficiency.

The discussion of diseases of the arteries by Roger and Gouget, which constitutes the second section, is not only rich in suggestions to the practitioner, but also in thorough accord with the most advanced doctrines. In the following section the diseases of the aorta are presented with considerable fullness of detail. An equally detailed account of the diseases of the veins is given by Widal and Bezançon. In a chapter on disease of the lymphatic system Bezançon deals chiefly with the role of this system in general and localized infections.

The final section, on diseases of the blood, by Parmentier, is prefaced with a description of the physiology and morphology of the blood, its changes in disease, and the methods of examining it. The author, ignoring the Thoma-Zeiss and Fleischi instruments, recommends the inferior and less convenient methods of Hayem. The presentation of the special blood diseases is thoroughly up to date; indeed, we must suspect that the author enjoys some insight into the future when he declares that the unity of leukemia and Hodgkin's disease (the doctrine taught by French writers generally) is "definitely decided."

A PORTABLE OPERATING TABLE (WEIGHING LESS THAN TWENTY-THREE POUNDS).

BY J. BENTLEY SUKER, M. D.,
ATTENDING SURGEON TO THE ALMS HOUSE HOSPITAL, NEW YORK.

About a year ago, acting upon the suggestion of Dr. F. H. Markoe of this city, I designed a light, portable operating table of bicycle tubing, with the special purpose of producing a table which could easily be carried by hand or in a coupe for operations in private houses, and yet should not sacrifice to mere lightness any of the essential features of a good and convenient operating table.

The definitive design has now been in use for some months and has proved to be so useful, because of the convenience with which it can be carried, the rapidity and ease with which it can be assembled or taken apart, the simplicity of mechanism, and the absence of loose parts, that I have been induced to publish its main features.

While extreme lightness has been aimed at in its construction, strength has not been sacrificed, for the table will sustain a weight of five hundred pounds, and extreme rigidity has been obtained by a system of sliding braces.

The dimensions of the table when set up are: thirty-four inches high, nineteen inches wide, and seventy inches long (see Fig. 1). These measurements are more or less arbitrary, and by arrangement with the maker the surgeon can have slight changes in dimensions carried out without material alteration in weight.

The material for construction of the standards and side bars is seamless steel bicycle tubing; the frame of the bed is made of angle iron and the bed itself of broad bands of thin steel arranged as lattice-work.

The bracing is carried out by means of four steel wires which cross diagonally from top to bottom of the standards. These braces are divided at the centre and held together by a steel collar which allows them to slide on each other. The bed of the table is made in three leaves and is detachable from the standards by merely releasing two thumb springs. It can then be packed in a space thirty-four inches by nineteen inches by two inches by folding the end leaves over the middle one, each end leaf being just one half the size of the middle (Fig. 2). The four side bars joining the legs are fitted at their centres with rule hinge joints which, by their toggle action, prevent any tendency to collapse when the table is set up, and the top bars are provided with thumb springs as an extra precaution. When these springs are released the side bars fold together, the diagonal wire side braces sliding past one another; the legs, being offset at the bottom, add to the stability
and at the same time allow them to fold more compactly. The standards thus folded measure thirty-four inches by eighteen inches by two inches, making the whole table, when packed, to occupy a space only thirty-four inches by nineteen inches by four inches (see Fig. 2).

All the positions ordinarily used in operating can be easily obtained with this table, and the change from one to another can be quickly effected without altering the position of the patient upon the table. By merely pressing down upon the foot leaf of the table the patient can be thrown into the Trendelenburg position in a moment (Fig. 3).

A turn-buckle attached to each of the sliding braces makes it possible for them to be readily set up, thus preventing the table from ever losing its rigidity.

29 East Forty-Fourth Street.

Miscellany.

What Asepsis in Surgery can do.—Dr. Byrom Bramwell (British Medical Journal, October 7th), in an address on Thirty-five Years of Medical Progress, referring to the advantages gained through perfect asepsis, says:

"Some two years ago a man was admitted to the Edinburgh Royal Infirmary, under my care, suffering from Jacksonian epilepsy. Drug treatment having failed to give any relief, the operation of trephining was performed by Mr. Cotterill. A portion of bone the size of the palm of the hand was removed. The dura mater was then freely opened. No gross lesion was detected, though the brain was explored in various directions with a trocar. The large wound in the dura was brought together by a series of catgut ligatures. The portion of bone which had been removed was then carefully replaced, and the scalp wound closed in the usual way, of course under rigid aseptic precautions. The wound healed by 'first intention,' and in the course of a few days the patient had completely recovered from the operation without the slightest pain, fever, or constitutional disturbance. Some three months after the operation the patient died in a fit. On subsequent examination it was found that the portion of bone which had been replaced was firmly and accurately united, the inner table being perfectly smooth and natural. The inner surface of the dura mater was to all intents and purposes absolutely normal. The catgut sutures remained in situ in a perfect state of preservation; indeed, they looked as fresh as if they had been introduced the day before. The wound in the dura was united so perfectly and accurately that it reminded me of a beautiful piece of needlework. I doubt whether the most expert seamstress, working with dead tissues (silk, etc.) outside the human body, could have produced a more perfect result."

The Bacterial Treatment of Sewage.—The Interstate Medical Journal for October says editorially that it is more than forty years since Pasteur demonstrated that there could be no fermentation without organisms. This principle has been discussed at some length by Mr. D. Pidgeon, who has shown that the invisible microbe is likely to solve the problem of the effective method of sewage treatment.

At the beginning of the present decade certain experiments were made at the town of Lawrence, Massachusetts, which prove that the success in the filtration of sewage depends upon the very slow motion of exceedingly thin films of liquid over the surfaces of particles having spaces between them sufficient to allow air to be in continual contact with the films of liquid; the presence is necessary, moreover, of certain bacteria to aid in the process of nitrification. The experiments further demonstrated the necessity for making the supply of sewage to the filter intermittent, while they afforded a percentage of purification such as had never been obtained before. Of ten filters employed, each containing a different material, four or five removed by oxidation ninety-five per cent. of the nitrogenous impurities contained in the crude sewage, giving effluents which included less organic impurities, as shown by chemical analysis, than most of the drinking-water supplies of the State. The Massachusetts experiments were speedily supplemented by others which were made in England. Notably Mr. Scott-Moncrieff began to study the "biolysis," as he termed it, of sewage, basing his investigations on the consideration that, since all effete substances can be dealt with by Nature without assistance from chemicals, the problem resolves itself into discovering such artificial methods as would enable this agency to deal with the impurities contained in sewage on any scale, however large, at a reasonable cost, without creating a nuisance, and without the use of chemicals. He devised a "cultivation tank," carrying a layer of flints about fourteen inches deep through which the crude sewage runs. This tank is really a nidus, suitable for the growth and multiplication of the anaerobic organisms—those, namely, that thrive in the absence of oxygen, and give rise to putrescent fermentation. The fresh sewage, not yet deprived in the sewers of all its oxygen, is attacked on entrance by aerobic organisms, which, as the supply of the vital element at their command in the influent becomes exhausted, leave what remains of the food supply to such anaerobes as find a congenial home in the airless layers of the flint bed. These so thoroughly complete the work of decomposition and final liquefaction that practically no sludge results, while the effluent contains all the solids and
liquids which were present in the raw sewage—resolved into simpler forms, indeed, but also deprived of a considerable proportion of the original impurities, which have disappeared by conversion into carboronic acid, marsh gas, hydrogen, and nitrogen. By supplementing the cultivation tank with a nitrifying chamber sufficient assistance is afforded to the aerobic organisms to permit of the process of nitrification being carried to such an extent as to produce a filtrate containing in solution enough nitrates to give it a commercial value. The chamber contains a series of shallow trays, vertically arranged and separated one from another by a few inches of air space. Each tray holds a layer of finely broken coke two or three inches thick, and the topmost of these is evenly dosed at regular intervals with such quantities of the tank effluent as would represent a flow of one million gallons to the acre to the twenty-four hours. The liquid falls through tray after tray until, on reaching the lowest of the series, it is found to contain, in every one hundred thousand parts, from seven to nine parts of nitrates; equivalent to the mineralization of ninety per cent. of the total organic matter contained in the effluent from the cultivation tank. If, as is predicted, the final product of properly biolysed sewage should contain such a percentage of nitrates as to render it a valuable plant food, it may not, perhaps, remarks Mr. Pidgeon, prove a mere inventor’s dream that there will presently gather around the sewer outlets of towns and cities acres of glass houses whose abnormally large production, whether of fruit, flowers, or vegetables, will more than pay interest of money on the original outlay.

Polyandry in Thibet.—The Indian Medical Record for October 18th says that in Thibet only the eldest son of the family marries, and the wife accepts the brothers of her husband as secondary spouses. The whole family is thus held to the home. The children belong to the eldest brother, while the younger brothers are lesser fathers. The natives are strongly attached to this custom, the women in particular despising the monotony of European monogamy, and “widow” is a term of reproach among them. Children are very obedient to their fathers and mothers, and the family feeling is strongly developed.

Vaccination and Small-pox.—The Journal of the American Medical Association for November 18th says that Dr. Gibbes, health officer of Detroit, Michigan, on November 11th visited those districts near Windsor, Ontario, where several cases of small-pox were reported, and recorded the fact that the disease had not attacked any but non-vaccinated people.

The St. Petersburg Institute of Experimental Medicine, according to the Archives de pathologie, cited in the Gazette hebdomadaire de médecine et de chirurgie for October 26th, has recently been provided with a laboratory for the study of the plague and for making plague antitoxine. It is situated in the fortress of Kronstadt, surrounded by water on all sides and capable of complete and immediate isolation. There is, however, communication with the city by means of a steamboat.

A British Ambulance for the Boers.—According to the British Medical Journal for November 11th, Sir James Sivewright, K. C. M. G., who was commissioner of public works in Cape Colony until last year, has been successful in organizing an ambulance party to go to Pretoria to assist in treating the Boer wounded. He defrays the whole cost of the equipment, and the Journal understands that a British line of steamers has arranged to take the whole party to South Africa free of charge. The ambulance party will be in charge of Dr. Gray, of Aberdeen, son of Brigade-Surgeon R. Gray. An Afrikander Home was established in connection with the Edinburgh University some years ago, and has been attended by some eighty students in the various faculties. One of these gentlemen, Dr. Neethling, who took his degree in the university this year, and has since been house surgeon to the Bradford Infirmary, is said to have resigned that appointment and will be one of the surgeons to the ambulance. Ten students from the Afrikander Home in Edinburgh will go out as dressers, and the ambulance staff will also include a nurse. In the selection of the equipment Sir James Sivewright has had the assistance of Mr. James Cantlie, F. R. C. S.

Professor William Osler and Professor Howard Kelly, of Baltimore, were, according to the Journal of the American Medical Association for November 18th, elected in October honorary members of the Royal Academy of Medicine in Ireland.

A Combatant Medical Officer.—We learn from the British Medical Journal for November 11th that Dr. Rossignoun, a Belgian medical officer in the service of the Congo Free State, is said to have done excellent work as a volunteer artilleryman at the capture of Redgaf in 1897. Lieutenant Saroléa and Sergeant Cajol, who were in charge of the guns, were killed, and as they were the only European artillerymen in the expedition the commanding officer was in a serious difficulty. But Dr. Rossignoun was equal to the emergency, and without hesitation proceeded to direct the service of the guns. This he did with such success that in recognition of his services the decorations of the Service Star and the Knighthood of the Royal Order of the Lion were conferred on him.

The March of Sanitary Progress.—According to Science for November 24th, Dr. W. H. Corfield, professor of hygiene and public health in University College, London, has been appointed to the newly created post of consulting sanitary adviser to the British Office of Works.

Deaths of Medical Men.—The deaths are announced of Dr. Walter J. Hoffman, of Reading, Pennsylvania, formerly a surgeon in the United States Army, who published many important ethnological researches on the North American Indians; Dr. W. C. Arison, professor of surgery in the University of Durham, England; and Dr. Gonzalo Aróstegui, formerly professor of surgery in the University of Havana.

A Memorial to the Late Dr. Müller, of Vienna.—According to Science for November 24th, a memorial of Dr. Müller, who, it will be remembered, fell a victim to the plague in Vienna on October 23, 1898, was recently unveiled in the quadrangle of the General Hospital of that city. Professor Nothnagel delivered an address.

Another Prince Physician.—The Indian Medical Record for October 25th informs us that it was expected that “His Highness, Sir Bhagwatsinji, G. C. I. E., M. D., F. R. C. P., LL. D., Thakore Sahib of Gondal,” was to return to India from England.

A CASE OF HOURGLASS STOMACH
(STOMACH EN BISAC)
OPERATION. RECOVERY.

By CHARLES GREENE CUMSTON, B. M. S., M. D.,
ASSISTANT PROFESSOR OF SURGICAL PATHOLOGY
IN THE FACULTY OF MEDICINE, TUTTS COLLEGE, BOSTON;
HONORARY MEMBER OF THE ANATOMICAL SOCIETY OF PARIS;
ASSISTANT OF THE PATHOLOGICAL SOCIETY OF BRUSSELS;
OF THE AMERICAN ASSOCIATION OF PHYSICIANS AND SURGEONS;
OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS;
OF THE AMERICAN ASSOCIATION OF SURGICAL PATHOLOGISTS;
ASSOCIATE OF THE PATHOLOGICAL SOCIETY OF PARIS;
MEMBER OF THE ACADEMY OF MEDICINE OF PARIS.

Miss W. S., aged forty-seven years, was first seen by the writer in March, 1898. At that time she was complaining of a severe pain in the right side and pain in the epigastric region and occasional vomiting after eating. The patient was a thin, anemic subject, in a rather despondent condition of mind. Examination revealed what was believed to be a dilated stomach in a state of ptosis and a right-sided ren mobilis.

On the supposition that this was a case of gastroparesis and gastrectasis, the symptoms of which were exaggerated by the presence of a very movable kidney, nephropexy was performed a few weeks later, with the result that the pain in the right side was completely relieved, but the digestive symptoms continued quite as before.

In November, 1898, the patient was again seen, complaining bitterly of her stomach, and a more careful history of the digestive disturbances was obtained, a thing that should have been done in the first place, as the symptoms were far too marked to have been neglected as they were.

At the age of seventeen the patient had typhoid fever and had suffered ever since from what she called indigestion; but at about the age of twenty-six attacks of pain in the epigastric region and vomiting began to occur, and have been more or less constantly present ever since. The attacks of gastric pain occur more especially after a hearty meal, excessive bodily exercise, or mental fatigue, but at no time was there any blood vomited or passed per rectum.

The menses have always been regular and painless. Chronic constipation of severe grade has been present for many years, and the patient has frequent attacks of frontal neuralgia. The heart and lungs are normal. Analysis of the urine gave the following results: Specific gravity = 1.016; total amount in twenty-four hours = 1,200 cubic centimetres. Color pale. Reaction slightly acid. Urea, 25.5 grammes to the litre. No albumin nor sugar. Abdominal viscera, excepting the stomach, in apparently normal condition.

I would here remark that the patient’s father died at the age of fifty-one of some obscure stomach trouble, from which he had suffered for many years.

As has been said, a dilated stomach had been diagnosed when the patient was first seen, but we now suspected that the gastrectasis was quite probably due to a benign, or perhaps malignant, stricture of the pylorus, because palpation of the mass could be detected in the left hypochondriac region, which had not been noticed when the patient was examined in March. The splashing sound could be elicited, but auscultation over the back when the patient swallowed water only showed the characteristic normal glou-

glu sound. When the stomach had been moderately distended with CO₂, its lower border was found at about a finger’s breadth below the umbilicus. The lower half of the abdomen was retracted.

The vomitus obtained during an attack of pain was a yellow mucous with a decided acid reaction. The stomach was irrigated and a test breakfast, consisting of a cup of tea, one egg, and a roll, was ordered, and the stomach contents were withdrawn two hours later. They were found to be composed of fluid containing about twenty-five cubic centimetres of the roll. After filtering, the analysis showed a considerable amount of free hydrochloric acid and a complete absence of lactic acid.

An exploratory incision was advised and accepted.

The stomach was irrigated morning and evening with a 1-to-1,000 solution of naphthol β for one week prior to the operation, which was done on December 2, 1898.

An incision twelve centimetres long was made, beginning at the outer border of the rectus muscle, midway between the tip of the sternum and the umbilicus, and was carried obliquely downward on the left side. When the abdominal cavity was exposed the pylorus was examined and found perfectly normal. At about the junction of the lower with the middle third of the lesser curve of the stomach was found a stricture portion uniting a normal lower third with a dilated upper two thirds of the viscus. The strictured portion was about seven centimetres wide and three centimetres long, and was united to the surrounding structures by a few tough adhesions. These were broken down by the finger and a few snips of the scissors and the part liberated.

After the stomach had been well drawn out through the abdominal incision, an incision was made on the anterior aspect of the viscera in the longitudinal axis of the strictured portion. The stenosed portion would allow the passage of three fingers. The incision was continued upward and downward for about four centimetres, and when completed measured about eleven centimetres. A Heineke-Mikulicz plastic operation, as devised for the pylorus, was done, and when completed the line of union was about eleven centimetres long.

The borders were brought together by fourteen interrupted fine silk sutures which were passed through the stomach wall, but did not include the mucosa or the peritoneum. The silk sutures were covered by bringing the peritoneum together with Lembert’s suture of fine catgut.

The peritoneum, fascia, and muscles were sutured with fine chronic catgut, the skin and fat being united with aluminum and bronze wire. The two figures here
THE EARLY DIAGNOSIS
OF ANEURYSM OF THE ARCH.*

By WILLIAM PORTER, A. M., M. D.,
ST. LOUIS,
PHYSICIAN TO THE ST. LOUIS PROTESTANT HOSPITAL;
TO THE THROAT AND CHEST DEPARTMENT OF ST. LUCY'S HOSPITAL;
PHYSICIAN IN CHARGE OF
THE MEDICAL DEPARTMENT OF ST. JOSEPH'S HOSPITAL;
FORMERLY ASSISTANT TO DR. MORELL MACBREIGH.

My subject is one that in its entirety is not within the limits of the definite work of this association. So important, however, are the laryngeal symptoms in many cases of aneurysm that it is now well understood that a diagnosis in cases of suspected arch lesion is not complete without laryngoscopic investigation. Thus it is that I do not hesitate to speak of this subject here, and even to emphasize some methods of interrogation not wholly within our special domain. Those of us who have much to do with the physical examination of the chest well know that there is nothing more difficult than to make a conclusive diagnosis in some of these cases in which the lesion of the aorta is comparatively small, and yet there is no class of cases in which the prognosis is more important.

It is not my purpose to review the whole field of physical exploration, or even to note very fully the more easily recognized symptoms, often so apparent in well-developed aneurysm, but rather to refer to some special points not made prominent in the text-books and to mention one or two suggestions that are almost, if not altogether, new.

While many signs are more or less important, and several of these, combined, may warrant a diagnosis, yet there is only one phenomenon positively characteristic of thoracic aneurysm, and that is the presence in some part of the chest of a pulsating tumor other than the heart, which beats isochronously with the heart, and at least as forcibly, and which at each impulse expands in every direction (Balfour). In this connection it may be well also to remember that the aneurysmal pulsation is usually more forcible than that of the heart.

In the study of the evidences as presented by the average case of aneurysm, the laryngeal symptoms will naturally interest us at first. Let me at the outset recall the fact that pressure upon the recurrent nerve from aneurysm or thoracic tumor does not necessarily produce aphonia. I deem it of value to mention this because it is to be noticed that in many clinical reports the statement is made that the laryngeal evidence was negative because there was no aphonia.

The phenomenon of compensatory arytenoid movement (which formed the basis of a paper by the writer before this association in 1895) is now sufficiently established. The laryngeal image may be seen to be normal in appearance and function except in one respect—where there is paralysis of one recurrent nerve, most frequently the left, the corresponding cord may be seen in the cadaveric position, while the opposite cord may cross the median line and phonation be possible.

In such cases, however, it is impossible that equal tension be made on both cords, and the unequal vibration will produce decided change in the voice—a hoarseness (W. T. Porter), a monotone, and inability to reach a high note (Newman, Mulhall). One or all of these symptoms may be present. Sometimes at the beginning there is not even a loss of movement, but a congestion, consequent, doubtless, upon laryngeal irritation. The only subjective symptom at this stage may be a more or less constant laryngeal cough. In some of these cases, the pressure upon the nerve being increased by the growth of the aneurysm, complete aphonia results.

It has been noticed that a bilateral adductor paralysis may be present when only one recurrent nerve is involved. It is possible (Dr. George Johnson) that one recurrent centre takes on increased and compensating action when the other fails, and, being stimulated beyond the normal, it too may, in time, fail in its function.

The dyspnea of aneurysm, though not a constant symptom, presents many phases and should not be overlooked. When it is distinctly laryngeal, it is associated with and dependent upon motor paralysis of one or both sides. Sometimes the narrowed glottis is still sufficient for easy respiration during quiescence, but exertion produces greater inspiratory demand, and during the effort the paralyzed cords are drawn violently downward and inward, with resultant aphonia.

There may also be dyspnea (as so well demonstrated by Newman), not only from direct pressure upon the
trachea and bronchi, but from pressure on the bronchial plexus, with consequent bronchial spasm. In one case this was the only form of dyspnea present that I could discover, and this was increased in certain recumbent positions.

Tracheal tugging and tracheal pulsation as well as dysphagia may appear, the latter varying in intensity at times, but generally at a stage when there is other and more positive evidence, and these have received as much prominence in our books and journals, as, in the present state of our knowledge, they are entitled to. The Röntgen rays give us an interesting field for study and may be of more use in the future. So far, the best pictures are, of course, those of advanced cases in which the ordinary methods of investigation are adequate, but I believe that we will have better results and definition in much earlier cases.

Pain in the region of the aorta is frequently referred to as a characteristic of aneurysm, but I have not found it a valuable or constant indication. The pain of pressure and tension, so often mentioned in the books, is not only often absent, but is almost exactly simulated in many cases of neurasthenia—in fact, in the latter condition it is of frequent occurrence. One of the most prominent physicians of my acquaintance has borne the burden of the fear of aneurysm for three years on account of the presence of the so-called characteristic pain, while the most careful physical examination has failed to find one confirmatory sign.

Far more indicative and just as frequent, in aneurysm of the arch, is a pain in the region of the fifth or sixth dorsal vertebra. I well remember a case in which this was the only symptom, so far as I could learn, though I had no personal knowledge of the history, the patient, a man of forty years of age, dying from rupture a few minutes before my arrival. He had been treated by a noted neurologist for spinal irritation, and the autopsy showed vertebral caries from pressure. This pain may also be found in the neurasthenic, but in these cases it is lower, opposite the solar plexus, or, as a point of second selection, about the fifth cervical.

Passing the mention of the evidence to be gained by percussion and palpation and much of what is already formulated as the results of auscultation, I wish to call attention to two points which should be remembered in every suspected case. Auscultation of the left intercostal space may reveal an arterio-diastolic murmur not heard elsewhere, or there may be here or in the neighborhood a systolic murmur, due to the beating of the aneurysmal sac on the left bronchus (Gerhardt). It is heard at the same point as the pain above mentioned.

The second auscultatory phenomenon, not as yet prominently mentioned in the text-books, is the presence of a systolic sound or thud in the brachial artery, synchronous with the systole of the heart (Glasgow). Skoda and Clark have both called attention to this sound as significant in aortic insufficiency, and Dr. Glasgow well says that the same factors which are necessary to produce it in aortic regurgitation are equally necessary and often present in aneurysm.

I now wish to put on record a method of examination with which I have been experimenting for about three years. Remembering the close proximity of the aorta to the esophagus, and that the latter is exceedingly elastic and compressible, it occurred to me that a large bougie, with the lower end made very distensible, could be passed down opposite the site of suspected aneurysm, and the impulse conveyed to the distal end of the tube and measured. The procedure is a very simple one. The ordinary esophageal bougie can be covered at the end with gold-beater's skin, and, after a little spraying of the pharynx with a weak cocaine solution, it can easily be passed without danger of violence to any thoracic lesion.

The tube is then distended with water and connected with a U-tube, which is also filled with water. A few drops of coloring matter will add to the demonstration of the experiment. If the tube is passed down near the cardiac orifice, the heart impulse is sufficient to produce some vibration in the tube, especially if there is hypotrophy; but if the tube is placed approximately opposite the aortic arch, very little impulse is noted in the normal case.

Where there is aneurysmal distention and impulse at this point, it is not difficult to get a more or less distinct vibration, which can be seen and estimated in the bent glass tube. In five out of seven cases under observation during the last three years the impulse could be noted by this method. I need not weary you with the details of the histories except to say that in three of these cases there was a doubt at first, even after repeated investigation by the usual methods.

I had hoped to be able to claim originality for this, but I have just found, through the kindness of Dr. Abrams, of San Francisco, that Schnell (Münchener medizinische Wochenschrift, July 23, 1889) has written of a method which, though not exactly the same, is certainly entitled to precedence.

More recently I have been experimenting with the auscultation of aneurysm of the arch by way of the esophagus, which, so far as I can learn, is original, although my former experience makes me hesitate to say even this. A solid esophageal sound with a cylindrical end, something like the well-known dilator, but with a much longer tip, is passed in the usual way. To the outer end a hard-wood disc is screwed. To this disc is applied a stethoscope, or, what I have found much better in every way, the autoscope devised by Dr. Outten and recently given to the profession. In this little instrument the sound vibration is caught and magnified by tightly stretched animal membrane, inclosed in an aluminum case, open on one side, with rubber tubes attached to aural tips. It promises to be an improvement
on the stethoscopes in that there is not only a better conduction of sound but a clearer definition. Through the dense medium of the solid bougie the bruit is conveyed to the disc with great plainness. The vibrations of the latter are then determined by the autoscope. The procedure is not difficult, but, having used it only during the past winter, and in but three cases, I am unwilling as yet to compare it with the usual media of auscultation through the thoracic wall. In two of these cases the arterial bruit was certainly more distinct and positive.

3886 Washington Boulevard.

FIBRO-LIPOMATOUS TUMOR OF THE EPIGLOTTIS AND PHARYNX. 8

By E. Fletcher Ingals, M. D.,

CHICAGO.

Mr. S. W., aged twenty-eight years, a farmer, was referred to me early in February, 1899, on account of difficulty in breathing, speaking, and swallowing. He stated that in 1894 he had noticed a little difficulty in breathing at night; that some time later his voice became muffled, and that in 1896 he began to have much trouble in swallowing because of some obstruction in the throat, which, however, was not painful. In September, 1896, a growth, said to have been upon the base of the tongue, had been cauterized several times and efforts had been made at its removal with scissors and snare, by which small pieces had been taken off. This had given him some relief for a few months, but afterward he had gradually grown worse. During the two months preceding the time when he first saw me the throat had been gradually filling up, causing more and more difficulty in swallowing, but interfering especially with breathing when he was lying down. His voice was much muffled at the time I saw him on account of some obstruction which was not visible on inspection of the throat with a tongue depressor. He was breathing fairly well when sitting quietly, but had much difficulty when lying down. He had not suffered from previous disease, excepting rheumatism in 1890 and 1894, and some of the diseases of childhood. There was no evidence of hereditary predisposition to any disease. His weight was normal, pulse and temperature normal, appetite and digestion good. There was a little cough for the purpose of clearing the throat, but no expectoration. There was no evidence of pulmonary disease. The nasal cavities were normal; oropharynx, tonsils, and palate also natural. Upon examination with a throat mirror I found a large tumor with a smooth, somewhat congested surface nearly filling the laryngo-pharynx and apparently attached to the right two thirds of the base of the tongue and to the right side of the pharynx. This left only a small chink about a quarter of an inch in width at the left side of the laryngo-pharynx when the throat was in a passive condition. It was impossible to see anything below this tumor excepting the pyriform sinus and the pharyngo-epiglottic fold of the left side. I suspected that we had to deal with a fibrous tumor attached to the base of the tongue and side of pharynx. The patient was presented at my clinic in Rush Medical College, where the parts were anæsthetized by a spray of a ten-per-cent. solution of cocaine and a No. 5 steel wire loop was passed about all of the tumor that could be engaged, which seemed to be the greater part of what was visible. The wire was tightened with the snare, but when the milled wheel was turned down to cut off the growth, the resistance was so great that the wire broke. Twice subsequently similar wires were used and both of them broke, so that the operation had to be given up for the time being. I became satisfied that the ordinary polygons snare would not be strong enough to remove the tumor, therefore, a week later, with a uterine écrousur, which I had bent at nearly a right angle, and which was armed with a No. 8 piano wire, I again engaged the upper part of the tumor, that had been formerly caught, and I had no difficulty in cutting it off, removing at the first operation a mass about an inch and a half by an inch in its various diameters. This was covered with a smooth mucous membrane, was firm, and had all the physical characteristics of a fibrous tumor. Immediately afterward I removed another piece, about a third as large, which had the same characteristics, but I found that there was still a large mass lower down, so that the operation gave the patient only partial relief. The effects of the cocaine having worn off, the patient wished to defer further operative procedures for a few days. His throat was necessarily quite sore for some days afterward. He returned to me in about ten days, when I removed another mass an inch and a quarter by half an inch in its various diameters. This had all the appearance of a fatty tumor. A week later I removed two masses each about half an inch in diameter, and a week still later another not quite so large. As the lower masses of the tumor were removed, it was found that it had been attached to the upper portion of the right side of the epiglottis, to the right pharyngo-epiglottic fold, to a part of the base of the tongue, and to the right side of the pharynx. The lower portion of the larynx was now found to be normal, and all the uncomfortable symptoms had disappeared; but a small bit of the tumor remained in the right valicula, which I could not engage in a snare. This I cut away with cutting forceps and cauterized the part thoroughly with the galvano-cautery; thus the growth was entirely destroyed. The patient was discharged, but agreed to report a month later. The growth was examined microscopically by Professor Heetoom and his assistants in the pathological laboratory of Rush Medical College. The first mass removed was found to be a typical fibrous growth, another part had the mixed fibro-lipomatous characteristics, and the last large mass was a distinctly lipomatous tumor.

May 24th.—The patient came into my office this morning, the first time since his discharge, and I have the opportunity of seeing the sequel. The right side of the epiglottis is shown adherent to the side of the pharynx and partly to the base of the tongue, but there has been no return of the growth. The adhesions of the epiglottis would appear to prevent it from closing the larynx in deglutition, but Nature has adapted the parts to the new conditions, so that he has no difficulty in swallowing.

The Second International Antitobacco Congress will be held in Paris next year, in connection with the exposition.

* Read before the American Laryngological Association at its twenty-first annual congress.
VENTRAL FIXATION OF THE UTERUS WITHOUT LAPAROTOMY.

By FRANK SUGGS, M. D.,
LITTLE ROCK, ARK.

Various operations are performed in cases of uterine retroversion to replace and hold the uterus in its normal position. Among the most popular of these is fixation or suspension to the abdominal wall. This may be readily done through the vagina if a suture carrier such as I shall describe is used.

The posterior incision is preferable, and Douglas’s pouch is opened in the usual way. Uterine adhesions are broken up with the finger, and the ovaries and tubes are examined and treated as indications demand. With two fingers and a tenaculum the uterine fundus is then brought down backward through the opening in the vaginal vault. Two silkworm-gut sutures are placed, preferably in the anterior uterine wall, and the surface sacrificed. Artery forceps catch the ends of the sutures and the fundus is pushed back into the peritoneal cavity. The patient should now be raised to Trendelenburg’s position.

The carrier used is simply a long, curved cannula, with a strong, flexible trocar that may be thrust out several inches beyond the bulb-pointed cannula, and having an eye near the point for threading. The point is projected from the bulb, and the two ends of a long piece of medium silk are threaded in the eye and the point drawn back into the cannula. This leaves a free loop hanging down by the instrument. Into this loop is placed one of the silkworm suture ends that are in the uterus and twisted.

Two fingers are directed upward and forward through the vaginal incision toward the abdominal wall, which can be reached when pressure from without is made. The bulb-ended suture carrier is introduced along in front of the fingers to the abdominal wall, and the needle is thrust through, carrying the silk with it, which is then unthreaded, and in its turn draws the a mine of interest as regards etiological investigation. But to return to the patient whom we left resting comfortably on the evening of November 17th:

November 18th, 9 A. M.—Patient had continued to rest very comfortably during the night, at one time sleeping four hours on a stretch. Respiration remained at thirty and thirty-two per minute; very little pleuritic pain or cough. Pulse had remained at 112 and 116, strong and full, until this morning, when it had begun to exhibit some unsteadiness again at intervals, and cough and pleuritic pain were becoming troublesome. Sputum was rusty. Physical examination showed very good heart action, numerous rales over the consolidated lobe, pleural friction only barely discernible, and flat-
ness on percussion seemed about the same as on the preceding evening. Hot air given with same result as at that time.

**Same Day, 9 P. M.—** Patient had slept the greater part of the day. Pain had been present only slightly and infrequently, and no cough at all except on taking a deep breath or talking. Had perspired freely. Heart action strong and steady; numerous râles over consolidated lobe; no pleural friction audible. Percussion showed flatness decreased to dullness, and lung was evidently in process of rapid resolution. Pulse, 100; respiration, 32; temperature, 100.6° F. Hot air was applied, making twice to-day.

**20th, 9 A. M.—** Patient's condition eminently satisfactory in every way. Lung rapidly clearing, no pleurisy, and little cough. Pulse, 100; respiration, 30; temperature, 99.8° F. Hot air was postponed until evening.

**Same Day, 9 P. M.—** Patient's general condition practically the same as in the morning. Râles diminishing and dullness confined to one small portion of lobe affected. Pulse, 112; respiration, 34; temperature, 100.6° F. Hot air given.

**20th, 13 M.—** General condition essentially the same as yesterday. Dullness entirely absent, but râles still audible over the spot from which dullness disappeared last. Considerable bronchitis has developed over left upper lobe, but no dullness. Cough about the same as yesterday. Pulse, 106; respiration, 30; temperature, 99.8° F. Hot air given for the last time.

**21st, 4 P. M.—** Patient's general condition unchanged. Slight cough obtains when he talks much. Physical examination betrays nothing abnormal in the previously consolidated lobe. Condition of left upper lobe about the same as yesterday. Pulse, 102°; respiration, 28; temperature, 100.4° F.

The patient's recovery from this point, which ended the connection with the case of hot air, was very slow and protracted, due, I suppose, to the terrible strain upon his vital powers of the siege he had sustained. This case exemplifies pretty thoroughly the influence of the thermal agent in pneumonia, and what I now look upon as the indications for its administration—viz.: the occurrence of pleurisy, to relieve the pain of which opiates are usually employed; a harassing cough, which aggravates pleuritic symptoms and saps nervous energy, also ordinarily combated with opiates; and impending cardiac paralysis, precipitated by massive exudate, in the relief of which strychnine, whisky, and digitalis, singly or combined, have constituted our chief measures in the past.

The advantages it possesses over these are, in the case of opiates, that the victim's metabolic activities are maintained unimpaired, thereby giving him greater power to eliminate the disease and its noxious products from his system, and to recover from the subsequent debility, and that his nervous system is not subjected to the drain of energy due to the secondary increase of irritability which follows their immediate sedative effects.

As regards cardiac stimulation, when fatal distention of the ptomaine-impaired viscus is threatened by massive exudate, the same line of reasoning applies here as in typhoid fever, in the course of an article upon the treatment of which disease, appearing in the *New York Medical Journal*, issue of October 24, 1896, I discussed the subject in that connection. We must consider that every application of a whip is followed by increased exhaustion when the increase of function caused by the whipping has subsided. To overcome this, a fresh whipping and a more vigorous application of the same is demanded to produce the requisite amount of functional energy. This can be kept up but a short time without exhausting the powers of responding to stimulation to such a degree that the cardiac function sinks overwhelmed by the combined effects of stimulation reaction, ptomaine toxicity, and massive exudate distention, and, if it does prove possible to force the patient up to the top of the hill and over, his progress down the gentle declivity toward recovery is hampered by the necessity of overcoming the accumulated secondary depressions of successive stimulations as well as by the ravages of the disease.

Fortunately, in pneumonia the crisis calling for cardiac stimulation is usually brief, and the victim is able to respond to the whippings sufficiently well and for a sufficiently long period for us to carry him over, but not always. Hot air will enable us to save a large proportion of those who succumb to these conditions, because we have preserved for their use an amount of vitality represented by the sum of the stimulation reactions, it having rendered the whip unnecessary, and because, in addition, instead of driving him over a hill we have leveled the hill and he does not have to climb. Dry heat of high degree acts upon the exudate itself, removing the direct cause of the cardiac disturbance, which thereupon subsides. How much of its happy effect in this connection and on the cough is reflex I am unable to say. I am not yet clear as to the rationale of its action.

The report and analysis of failures are just as valuable in the consideration of a measure as the successes, hence a few words bearing in this direction will not be out of place. There are spread upon my records four cases of rheumatism in which I have not been able to attain a satisfactory finale, but in only one of them can the failure be interpreted as indicating weakness of the thermal element of treatment. This was in the case of a young man, twenty-nine years old, employed in a rubber-shoe factory. The disease was chronic and located in the deep muscles of the lumbar spine. I had been treating him medicinally for a month with very slight improvement, and then started him in on hot air. The treatments were repeated at intervals, alone and in connection with various drugs, for five months. The pain was always relieved at the time, and would sometimes remain away for five days, but so far has always returned at the end of a short period. It is much less severe than formerly, and the last time he called upon
me, three weeks ago, he said that if it never was any worse than it had been for the preceding month he "could get along with it all right." Why it is so persistent I am not able to say, but his occupation may have something to do with it. The fact remains, however, that a vigorous dry-heat regimen, alone and accompanied by drugs, has utterly failed to totally eradicate the trouble.

The first of the other three failures was with a lady, seventy years of age, attacked by acute inflammatory rheumatism in the wrist, which soon after involved the elbow and knee. She took three treatments accompanied by antirheumatic drugs, with complete relief of pain each time, and at the end of this period the swelling was nearly gone and marked progress was being made toward recovery. She then decided that she could not afford any more treatments, and, in spite of my warning that she would certainly have a return of the trouble if she did not persist in obtaining a cure, she discontinued. I have since learned that my apprehensions were fulfilled, and that she did have trouble, and much of it, subsequently. I was well aware that her poverty existed in her imagination rather than in reality, and, as my time was then very fully occupied with others, I could not treat her for nothing, and lost sight of the case.

The second was in a man, fifty years old, a great lover of beer. The disease was chronic, located in the lumbar muscles, and had existed for seven years. All alcoholic beverages were interdicted, and antirheumatic drugs administered simultaneously with the treatments, which always gave him immediate relief. Two or three would secure freedom from pain for a period of four or five days. Then he would go back to his beer again and the pain would reappear. This was repeated three times, but he was unable to resist his seductive beer more than a week at a time, and I finally gave it up.

The third and last was in a woman, twenty-eight years old, who had suffered from acute and subacute rheumatism in elbow, knee, and ankle for three months, and who came to me at the suggestion of the patient whose experience I have recorded in Case III. At this time the trouble had settled in both feet, medio-tarsal articulation, and she had been unable to leave the house for three weeks. I gave her medicinal treatment for a week, desiring to save her the expense of hot air if possible, but the results were unsatisfactory. I then gave her the treatments in addition to the drugs, and she immediately began slowly but steadily to improve, until at the end of two weeks from this time, after taking eight treatments, she was able to get about with no pain except for three or four minutes on beginning to walk after having kept the joint at rest for some time, and for two periods of twenty-four hours each had had no pain at all.

She then decided that the hot air was "not doing her any good," as she felt "good one day and bad the next." I endeavored to point out the benefit she was deriving, but she evidently demanded an immediate result, for she exclaimed that "Mr. — (Case III) got well in four treatments," and was not at all pleased because she had not been as fortunate. I attempted to convince her that all cases of rheumatism could not be induced to recover in the same length of time or by the same succession of events and sensations, but, as she expressed it, she "had lost faith in the hot air," and the result was discontinuance.

In this case the pain was provoked only by motion, being entirely absent when the joint was at rest, hence the treatment showed no immediate result. Its effect was manifested only by the manner in which the drugs took hold after I commenced its use. I was greatly disappointed at her discontinuance, as the unflagging steadiness of her improvement was a very positive indication that the victory was surely approaching.

About a month afterward my unheeded warning, that failure to persist in obtaining a complete cure would probably be followed by a return of symptoms, was fulfilled, and she suffered from an exacerbation involving several joints. The attending physician told her that my hot air had "spread the rheumatism all over" her body. Previous to learning that he had expressed this opinion, I had not regarded it as necessary even to mention to physicians, much less to deny, that antediluvian belief in the power of an external application to "drive" rheumatic inflammation from an active focus to other parts of the body, and I do not now consider that it merits a discussion.

I am induced by the above incident, however, to state for the benefit of other disciples of the healing art who might rest under this delusion, if there are any, that the simultaneous or successive involvement of different parts of the body containing the material favorable to the growth of the rheumatic micro-organism is a part of the natural history of the affection, whether gonorrheal or de facto; is a very commonly observed phenomenon under any line of treatment or without any treatment at all; that no local measure is required for its induction; and, lastly, that neither hot air nor any other local therapeutics is capable of precipitating the same. As might be expected, however, the fallacy is common among laymen because of their crude and erroneous conceptions of disease processes.

On May 15, 1899, I was called to a case of sepsis post-abortum. Pulse was 112, respiration 30, temperature 100.6° F. Slight tenderness was evident on deep pressure over uteri and left Fallopian tube, but peritonæum was not involved, and, except slight headache, the patient was entirely free from pain, and remained so throughout her illness. Thorough curretting was done, removing a large amount of infected débris, bowels opened freely with magnesium sulphate, milk diet ordered, and ungüentum Credé rubbed in
twice daily for four days. The patient grew steadily worse.

At this point I recalled my experience with Case VI, and began applying hot air. The patient ceased her downward progress after the first treatment, but the tenderness on pressure was not affected in the least by it. I continued the applications for four days, but, as the patient’s general condition remained stationary, and as I could perceive no difference in the local pathology, I then abandoned them. The next day she was slightly better, and this inaugurated a slow recovery, which extended over a period of eight weeks. I look upon the administration of hot air in this case as an unmitigated failure. It is possible that it had something to do with the arrest of the process, but I am more inclined to consider it coincident. Perhaps the streptococcus is less susceptible to heat and stimulated tissue metabolism than the gonococcus.

I may say, in passing, that this was the second patient on whom I had seen Crédé’s ointment used with absolutely no effect. The other was a case of the same sort, which I saw in consultation, and in which I recommended its use. The victim was very ill at the time, and, although three, and sometimes five, inunctions daily constituted the regimen, she steadily sank, and died a few days later. I have observed its use in no other cases.

In pneumonia hot air has not yet failed once to give me the desired result, the only case I have lost being a lady, eighty-one years old, who had been ill five days when I first saw her, and upon whom the use of hot air was a physical impossibility because of a peculiar combination of circumstances obtaining at that time. I do not think it would have altered the fatal issue anyway.

The gratifying results which I had obtained in this disease awakened my desire to ascertain what it would do in phthisis pulmonalis, but in well-established consumption I have not observed that it produced any effect whatever upon the main features of the disease. It does result, however, in a marked lessening of the cough, thereby allowing the victim to sleep and rest; the night sweats diminish, the appetite improves, and it has thus far in my experience invariably extinguished the painful secondary pleurisies in from twenty-four to forty-eight hours. It has therefore considerable value as a palliative measure, but for this purpose it will be chiefly available in sanitarium, as so many treatments are required that the expense becomes too great for the ordinary individual. The pathological processes appear to continue, lung tissue breaking down, and cavities forming, just the same with as without it. In inipient cases it promises better, but of this more anon.

In two cases of chronic nephritis I have observed no effect whatever, except in one the temporary alleviation of a dull, throbbing ache in the region of the kidneys, which sensation did not obtain in the other. I have said nothing about the rationale of the action of hot air because I have not yet reached a satisfactory conclusion in regard to it. So far, as soon as I have formulated one theory, I have observed a new phase of its action which has rendered the explanation untenable. It requires further observation and study. One element in this problem, however, I shall consider here, and that is the prevalent idea that a difference exists between the direct therapeutic effects of dry and moist heat, dry being stimulating and moist relaxing. I think this is unquestionably a fallacy.

Moist heat affects the non-vascular and only visible portion of the integument differently from dry because it macerates it. The parts beneath this, however, are continually bathed in and permeated by fluids, and when the heat has penetrated thus far it necessarily becomes moist, however dry at the surface. Again, it was not possible to maintain a dry heat of the surface of the body previous to the recent adoption of air as a medium of application, because, as I stated at the beginning of this article, a heated substance, dry in itself, rapidly induces perspiration where applied to the skin, which accumulates at the line of contact, thus transforming the originally dry into a moist heat. This would cause discomfort and, if the medium were hot enough, positive suffering, and the reflex phenomena of irritation dependent thereon are probably responsible for the existence of the fallacy.

It was known that moist heat could not be borne in great intensity; therefore it was not attempted to apply it hotter than was comfortable, and its maintenance even at this temperature was rarely attempted or possible of attainment. The dissipating influence of the circulation would soon reduce this to or near the body temperature, and this low degree of heat will produce relaxation whether moist or dry. It was also known that dry heat could be borne at much higher temperatures than moist, and its application would be attempted at higher levels. As we have seen, however, it would soon become moist and behave with the peculiar characteristics of moist heat, producing suffering which, was mistaken for a direct stimulant effect of the heat, which was supposed to be dry.

Finally, as it has been impossible until recently to produce a dry heat which would remain dry, it has been impossible to observe its effects, and hence we have not been in a position to know anything authentic about the differences between it and moist heat.

It is my intention in a future article to report and discuss results of the dry hot-air treatment in incipient phthisis, tuberculous peritonitis, tuberculous and other joint inflammations, syphilitic and traumatic periositis, syphilitic and varicose ulcers, pleurisy with effusion, neuritis, and various neuralgias. At the present writing, however, my experience with it in these affections is too limited and incomplete to render reliable deductions possible. I shall therefore conclude my pres-
ent consideration of the subject by summarizing as follows:

Hot air is a pain-relieving agent of unequaled value in those conditions where its application is indicated and possible, because of its very constant effectiveness, rapidity of action, and the absolute absence of deleterious after-effects.

In rheumatism, at least, its action is so profound in connection with judiciously chosen drugs that it may almost claim a positive curative power of its own, and may certainly be said to be the most powerful contributing agent we now know of. Many cases can not be cured by drugs without it, and in any case the victory over the ailment is much hastened and the patient maintained in comfort during the attack. On the other hand, we must remember that it appears to be rarely if ever capable of overcoming the disease without the aid of drugs.

It is capable of stimulating tissue repair to a remarkable degree, as is demonstrated by its effect upon sprains and, as I shall show in a future article, on at least many cases of intractable varicose ulcers.

It is capable of influencing most happily septic inflammations of serous membranes, as shown by its action in peritonitis and pleurisy.

It will many times at least give us the power of economizing nervous energy by relieving pain and other more or less dangerous conditions in pneumonia, thereby enabling us to refrain from sedatives and cardiac stimulation, and the nervous energy we may thus save for the patient will sometimes be sufficient to tide him over a crisis by which he would otherwise be overwhelmed.

We can not expect hot air or any other one measure to do everything. What I assert is that it will do a great deal, and that its powers are exerted in a direction in which we have hitherto been lamentably deficient; hence its addition to our armamentarium will enable us to increase by a large percentage the sum total of our power over disease. The capabilities which it has so far manifested, and we have as yet only begun to investigate them, are sufficiently weighty to justify belief that dry heat of high degree is destined to become in the near future a therapeutic agent of as great popularity as it possesses diversified applicability.

THE ARMY RATION.

By CHARLES SMART, M.D.,
LIEUTENANT-COLONEL AND DEPUTY SURGEON-GENERAL, U. S. ARMY.

Articles have appeared recently in the public press criticising the army ration, denouncing its unsuitability for troops in a tropical climate, and urging a radical change in its character. These articles are based on the elementary propositions that, while fatty foods are good where a high development of animal heat is required, they are harmful in a climate where there is no call on the system for a large heat production. Every reader is willing to grant these propositions. They are simple and can be verified every summer and winter by the inhabitants of the north temperate zone. There are twelve ounces of bacon in the army ration, and this is, no doubt, an excess of fat for a dictionary in the tropics. But it does not follow that the army ration should therefore be changed. The critics who see so clearly that the ration should be altered to suit their views of what is right and proper to be eaten in tropical climates, and who are astounded at the dullness of those army officials who think it wise to be slow in doing anything of this kind, do not appear to know that the army ration is run on a broader gauge than the elementary propositions which form the basis of their argument.

There is in the army of the United States a considerable difference between the ration of the soldier and the diet of the soldier. The critics of the army ration do not understand this. The ration is the allowance for subsistence of one person for one day. The diet is what is actually prepared in the kitchen for consumption by the soldier day by day. The ration is prescribed by law and consists of the meat, the bread, the vegetable, the fruit, the coffee and sugar, the seasoning, and the soap and candle components.

The meat component does not consist of fat pork or bacon, as those who know nothing of the domestic economy of army kitchens appear to believe. On the contrary, there is some variety in the meat component. It consists of twenty ounces of fresh beef, or twenty ounces of mutton when the cost does not exceed that of beef, or twelve ounces of pork, or twelve ounces of bacon, or twenty-two ounces of salt beef, or fourteen ounces of dried fish, or eighteen ounces of pickled fish, or twenty ounces of canned salmon, or eighteen ounces of fresh fish.

The bread component consists of eighteen ounces of flour, with baking powder when the men have to bake their own bread, or eighteen ounces of soft bread, or six ounces of hard bread, or twenty ounces of corn meal.

The vegetable components consist of two ounces and two fifths of beans, or two ounces and two fifths of peas, or one ounce and three fifths of rice, or one ounce and three fifths of hominy, and sixteen ounces of potatoes, or twelve ounces and four fifths of potatoes and three ounces and one fifth of onions, or eleven ounces and one fifth of potatoes and four ounces and four fifths of canned tomatoes, or four ounces and four fifths of other fresh vegetables, not canned, when they can be obtained in the vicinity or transported in a wholesome condition from a distance.

The fruit component consists of two ounces of dried fruit, such as prunes, peaches, or apples. The other components consist of coffee green or coffee roasted, or tea green or black, and sugar, or molasses, or cane
syrup, vinegar, salt, and black pepper, and to these are added the soap and candle components.

The slightest knowledge of practical cookery will enable any one who reads what I have just written to form an idea of what may be called the flexibility of the army ration. The soldier in the tropics is not called upon to eat his twelve ounces of bacon or go hungry. That or is not to be found in the regulation statement of the meat component of the ration, although there are more than half a dozen other important ors in it. And there is variety also in all the other constituents except the soap and candle components.

If the scientist will calculate the elementary constitution of any one of the various diets which may be formed from the flexibility of the army ration, he will find that there is a sufficiency of nitrogen and carbon in each to support the system of the soldier under the heaviest strain of work and exposure. If the proximate principles are calculated it will be found that many variations may be made in the relative proportions of proteins, hydrocarbons, and carbohydrates. But more than all this, we know that the soldiers of the United States have never gone hungry on their full ration.

Granted, then, that the ration suffices to sustain the system in the cold of a Montana blizzard, will any one suggest its insufficiency for nutritive purposes where there is little call for physiological fuel to keep up the animal heat? No, but, says the critic, for whose information I am writing, there is too much of the hydrocarbons, too much bacon in the ration to make it a suitable ration for tropical climates. Too much bacon! Too much candle! There is a candle component in the ration, but the soldier is not called upon to eat it. Nor is he required to eat the bacon if he does not desire to do so.

This leads me to refer to the elasticity of the ration. Its flexibility has already been referred to, but its elasticity also is wonderful. It is so elastic that the soldier may vary his meats if he does not require them for other purposes. He may leave the candles in the hands of the subsistence department, and, if their money value will pay for a can of peaches, or a pound of rice, or so much of any other of a long list of articles kept for sale by the subsistence officers, he can eat his candle component in the form of peaches, or rice, or any of the other purchasable things. So with the bacon. He is no more required to eat that because it is part of the ration than he is required to eat the candles, but he may transform it into some other article of food which he likes better or which is better for him under the climatic conditions which affect him at the time. So, indeed, with all the other components of the ration excepting only the fresh vegetables, fresh bread, baking powder, and dried fruit. Even the fresh beef component may be reduced in quantity, and the money value of the quantity not issued for use may be drawn in other articles on sale.

There is even a greater elasticity than this to the ration, for the money credit for components not drawn and used may be applied to the purchase of articles from outside sources—articles not kept for sale by the subsistence department. Thus, in probably every company and post mess hall in the United States on Thursday, November 30, 1899, there was turkey with cranberry sauce on the table, representing so much bacon and other articles of the formal ration not drawn in kind and used, but left in the hands of the subsistence department and placed as a cash credit for the payment for turkeys and cranberry sauce or for any other purchases to vary the diet of the soldier. If at any of the posts they did not have turkey and cranberry sauce on that day it was because these things were imposable there, but they no doubt had an excellent dinner all the same.

Under the pre-ent law and regulations as to the ration the soldier can have any variation of his diet within certain money-value limits which his officers consider necessary for his well-being. His ration is fixed by law, and it is a most liberal one; but his dietary depends upon the intelligent supervision of company officers and the ability of the company cooks. I have stated the law and regulations concerning the ration and its flexibility and elasticity, and the subsistence department may be depended upon to provide the articles necessary to vary the diet. If a change in the dietary is advisable, it lies with the company commanders to carry it into effect. If the change is desirable on medical grounds, medical officers should communicate their views to these responsible officers, and the change can be effected without difficulty. There is no need to talk about changing the ration to effect a change in the dietary.

But it may be said, Why not go a step further and reduce the ration to simpler terms? Why not make it a money value instead of so much of this, that, and the other component? A money value, to be of equal value at all military stations, would have to be a different value at every station. A dollar is worth nothing from the point of view of the ration if there is not a bite of anything within its purchasing radius; but to the stomach of a hungry soldier twenty ounces of fresh beef, twelve ounces of bacon, etc., have a fixed value, and when the subsistence department is charged with providing these articles the soldier will fare much better than if the department had only to provide him with so many cents a day for his food.

The United States army ration is the most liberal ration in the world. It is the best ration for the far northwest of this continent, whence come the subzero cold waves to sweep over the country from the upper strata of the atmosphere, and it is the best for the tropics when intelligently utilized. It is the product
of the experience of several generations of army officers, and it is the part of wisdom to be slow in urging alterations at the suggestion of people who know that an excess of fatty food is not suitable for a dietary in the tropics, and who have just discovered that there are twelve ounces of bacon in the soldier’s ration.

But the best dietary for the tropics is a wholly different subject from the ration, and we shall await with interest the publication of the observations of our officers—line and medical—on the modifications which appear to them to be judicious for Cuba, Puerto Rico, and the Philippines.

THE POTENTIALITIES OF THE PHYSICIAN.*

By KENNETH W. MILLICAN, B.A., M.R.C.S.

Permit me, if you please, to prefix my remarks with the statement that when I was invited to deliver this address I was considerably at a loss to fix upon a suitable subject. This may sound remarkably like a plagiarism, for I can not deny that many others have made the same remark before; but there is said to be a similarity in great minds which leads to their oftentimes arriving at the same conclusions and expressing them in similar phraseology quite independently of one another. And in the present instance I assure you that my statement is the result of my own unaided experience.

I pondered and pondered, and assured myself that had it been any other audience that I was called upon to address, I could, without doubt, have selected just the very topic for the occasion. For instance, I could have strung together an admirable array of moral maxims and philosophical platitudes to encourage a batch of newly fledged medical students. Or, again, by the aid of a Haydn’s Dictionary of Dates, an encyclopædia, and some of the literary réchauffés which can frequently be culled from the pages of the many exchanges which find their way into every journal office, I could have discoursed upon the history of medicine from preadamite times down to the end of the nineteenth century, and even have hazarded a few guesses to carry the audience prophetically into the advanced medicine of the twentieth; that would have been just the thing for a literary and philosophical society.

But, alas! on inquiring what was to be the occasion, and what the character of my audience, I was told that it was “just the usual annual address on the hospital memorial day,” and that the audience would be “mixed.” Now, the one subject preeminently suitable for such an occasion—a statement of the affairs and progress of the hospital, with, perhaps, a history of its origin—I at once realized would be ruthlessly wrested from me before my eyes by some inconsiderate func-

* An address delivered at St. Luke’s Hospital, Bethlehem, Pa., on the Memorial Day, October 18, 1899.
Anon comes the problem of a career. Many fields lie open to him: General practice in town or country; the services, army or navy; the mercantile marine; or, perseverance, employment to guard the health and repair the injuries of the employees of some great commercial enterprise—a plantation, a trading company in foreign parts, a mine, or what not; and, finally, there is spread out before him the alluring prospect of consulting or special practice.

The heart of the medical profession throughout the world undoubtedly pulsates in the great body of general practitioners. Often obscure, but painstaking and devoted, as a body they live lives whose usefulness is exceeded by that of no other body of men. Work may be arduous and grinding, fees may be small, holidays few, certain leisure none, fame afar off; but they live in closer touch with humanity as a whole than does all the rest of the world put together. If they are the right kind of men, their reward is a sure one, for it is locked in the faithful repository of their breasts, whence none can take it from them by force or fraud.

Of the services as a career but little need be said. They have advantages peculiarly their own, less marked, perhaps, in ordinary times in this country than in Europe, but by the law of compensation it follows that disadvantages peculiarly their own are theirs also. Government service is a certainty as regards pay, etc., it carries a special distinction of its own, and it affords a mode of life which is attractive to many temperaments for exactly the same reasons that make it repellent to others. A habit of subjection to discipline is a good thing, to at least some extent, for everybody; for it is rare that self-discipline is attained by those who have not been subject to the discipline of others. The services demand a special type of man, a man with a particular tone of character, if the candidate is not to find himself a square peg in a round hole. For those who like excitement and adventure they have in this country, during the past eighteen months, been afforded opportunities which have been eagerly seized. On the other side of the water such opportunities are always, as it were, in the air; consequently the military and naval services have all the time more of interest than, until the recent stirring times, they have had here.

Nor is the military career so profitless to the public advancement as many seem to imagine. By far the larger part of our knowledge on tropical diseases has been acquired by the patient labors of military medical officers; while the organization and method brought to bear in military administration make possible a system of collective investigation whose most recent outcome is the expedition to the west coast of Africa under the leadership of Major Ronald Ross, of the Royal Army Medical Corps, for the purpose of tracking the malarial mosquito to its ultimate domicile, and there learning how to entirely exterminate it.

The mercantile marine affords to a young man a very valuable chance to see the world. It is, moreover, a pleasant and not too arduous existence, though apt to become monotonous and wanting in opportunities for broad professional experience. It may be thought that the leisure and undisturbed peace of a long ocean voyage would afford opportunities at least for theoretical study. That is undoubtedly true—but there is something in the air in a sea voyage that causes the zeal for study to atrophy; and I can safely aver that, for my part, I accomplished more in a week in the way of study when I was a hard-worked country general practitioner than I did in months of ample leisure on board ship.

The larger ocean-going liners, however, especially the transatlantic ones, no doubt afford more practice; and also there are oftentimes good fees, good friends, and even occasionally, as I have been told, a good wife, to be gained on them.

Tea, coffee, and tobacco plantations in the tropics will probably soon offer to the junior members of the American medical profession, in the new colonies beyond the seas, opportunities which have long been enjoyed by their British colleagues; while for mining appointments they have many excellent openings in their own country as well as abroad.

It only remains to speak of the consultant and the specialist. Specialism is, of course, an absolute necessity. There is so much to know, so many kinds of dexterity to be acquired, that no one man can ever again be expected “to know it all.” But I can not help feeling strongly that no man should be accepted as a specialist until he has proved himself a general practitioner of ability and has acquired breadth, harmony, and, above all, a sense of proportion in his knowledge; and, further, that when he is a specialist he should aim at becoming the counselor of his professional brethren rather than directly of their patients.

In the towns, at any rate, I regret to say, the old idea of the “family doctor” is seemingly dying out. People nowadays prefer to employ a staff of special experts rather than to retain in intimate personal and family relationship one faithful, friendly, honest practitioner on whose judgment they can implicitly rely, knowing full well that when he says “Leave it to me,” all is well; and that when all is not well he will say, “I will call in Dr. So-and-so, and we will take counsel together.” Strange, is it not, that the age which has developed that general practitioner of commerce, the department store, where can be bought everything, from a packet of pins to a fully furnished house, to the impending ruin of the retail tradesman and the beggaring of the honest craftsman, should at the same time be using every effort to make life impossible for the general practitioner of medicine, by dividing up the dominions of the body among so many specialist physicians, as though it were a picture puzzle?
(b) The remuneration of the medical practitioner is rarely if ever a great one. He may make a very comfortable income—when he gets paid—and some may attain to comparative opulence. But there are no prospects, such as commerce holds out to its votaries, of vast incomes, nor even as compared with what may be accomplished at the bar does the medical profession rank high among remunerative pursuits. In this matter a grave difficulty confronts the practitioner of to-day—a graver difficulty, I venture to think, than in times not so many decades gone by. In avoiding the Seylla of unjust generosity at the expense of his own rights, and particularly of the rights of these dependent on him, the physician of to-day is in danger of falling into the Charybdis of commercialism. The medical profession must never be simply a business—it has sacred obligations which come down to us with all the weight of the purest ethics of antiquity to protest against that; yet, unless physicians can either all be financially independent or be supported by the state (neither of which alternatives is likely to happen), the medical art can not be practised, even by its most faithful devotees, on purely philanthropic lines. It is a pity, however, that public feeling in this and other countries is not high-minded enough to solve the difficulty in the way in which, according to a writer in the British Medical Journal, September 16, 1899, it is solved in Sweden. This writer says:

"As a contrast to this commercial spirit I should like to mention the professional sensiveness of the Swedish doctors, who do not even send in bills for their attendance. Most Swedish families send their doctor a check once a year, whether he has been in attendance or not during the year. The amount varies according to their means. The doctor does not send a receipt, but simply his card, with ‘many thanks and wishes for a happy new year.’ None of the commercial transactions mentioned are known."

The world is very apt to view the medical profession’s obligations—those due from it and those due to it—on the ‘heads I win, tails you lose’ principle. The medical profession is in its essence a philanthropic calling. Honorably and properly exercised, it should be above avarice, above self-seeking, above price. But the medical man has to live; and, unfortunately, the pure humanitarianism which is expected of the doctor when the baker lies in danger from an accident is not reciprocated by the baker when the doctor needs bread. If the doctor’s family were starving, his account at the baker’s long in arrears, and his cash and credit exhausted, no one would censure the baker who refused to supply him with the "staff of life." But if the baker were thrown out of his cart and seriously injured, and if the doctor, who had applied in vain for the remuneration due to him for years of previous work (even were it withheld out of unwillingness to part with money rather than from sheer inability to pay), were to refuse to attend the baker in his accident, what a howl there would be over the doctor’s "inhumanity"! The public sees in the medical profession two sides—on one hand, a humanitarian guild that exists for the benefit of suffering human nature, whose duty it is to shrink from no self-sacrifice under penalty of being branded as "inhuman"; on the other, a commercial occupation standing on the same business footing as does any other pursuit. And the public invariably decides, according to its own interests, whether the profession is to be regarded in a given case from its humanitarian or from its commercial aspect. Let me give an illustration: A medical man, years ago practising in an agricultural district, largely among the laboring classes, was compelled to let his bills run on to suit his patients’ convenience. A family of the kind that is ever ready to send, but never to pay, ultimately accumulated in three or four years a charge against them amounting to about $3—twenty-five dollars. As their family earnings probably did not exceed thirty shillings, say $7.50, a week, $5 was certainly a large bill to meet. But, since entreaty and expostulation from the doctor had availed nothing, and could not extract even a payment on account, the physician very reluctantly sued them in the county court. The magistrate practically dismissed the case by ordering the defendants to pay a trivial sum weekly, remarking that the doctor must have been a born fool to allow an account to run on like that with people in the defendants’ position, and adding, moreover, that he deserved to lose his money for not insisting on payment at the time of his visit.

Some months subsequently that doctor was summoned in the night by the same family. A child was very ill—at death’s door, so he was told, as he had been told many times before. Remembering his lesson from the county court judge, he demanded his fee, which was not forthcoming. He then declined to go until it was brought, and the child (who, as it turned out, was this time really very ill) died before the doctor arrived. An inquest was held, and the jury, apparently not agreeing with the sentiments of the county court judge, actually asked the coroner if it was not in their power to return a verdict of manslaughter against the doctor. Finding that that was impossible, they censured his "inhuman conduct," in which censure the coroner saw fit to concur!

From this it may be gathered that the conditions under which the medical man is expected to work are somewhat as follows: In reference to doing his work he is to be guided solely and exclusively by considerations of pure humanity, and any commercial spirit is to be sternly condemned; but, in reference to the acquisition of the wherewithal to live, his occupation is, after all, a matter of pure business, and if he can not look after his own interests, he can not expect others to do so for him. As I said before, "Heads I win, tails you lose!"
The financial remuneration of the physician, therefore, can never be expected to be very large, and must often be precarious and fluctuating to a greater degree than in most other occupations. He must expect to find self-abnegation and gratuitous services exacted from him such as would be expected from no other toiler on earth. But there is one comforting reflection even here. When we have a little surplus money, we pay it into the bank till we want it. When we claim it later, we do not look to get back the identical notes or coins which we paid in, but we receive others equally good, and with interest. And in like manner, so far as my experience goes, the deposits which we make into the Bank of Humanity come back to us with interest, not perhaps in the identical form in which we paid them in, but in others just as good, and at the time we most need them.

(c) The prizes open to our profession are, it must be frankly admitted, scanty and not exorbitantly valuable. A Chicago surgeon may have made, as stated, two hundred and fifty thousand dollars from the exercise of his profession alone, and not from inheritance or side issues in the way of speculation. No one will grudge him his good fortune, but rather all will congratulate him on his well-earned reward. But still, even two hundred and fifty thousand dollars, in an exceptional case, a prize in short, as the recompense of many years of arduous and unceasing labor, is not quite the equivalent of a railway magnate's fortune, or of that of an operator in north pole stocks, or a packer of bovine pathological specimens.

Then as to honors. In this country you are perhaps better off than on the other side, for there are but few opportunities, and those almost entirely official, of conferring artificial status. But in countries where they take men and make lords of them it would seem as though brewers and manufacturers and great men's secretaries and lawyers—particularly lawyers—were all better stuff to make lords out of than are doctors, though Lord Playfair and Lord Lister do exist as rare ACES of their kind.

But even in this country we have a surgeon-general of the army whose rank is only that of a brigadier, presumably because the medical department is of small account. Certainly it can not be by reason of any demerit on the part of the officer himself.

No! On mature deliberation I think we may safely say that prizes are few and insignificant, and blanks are many, in the medical lottery.

2. This brings us to our second subdivision, the potentialities of the physician toward others individually. Medicine is the individualistic profession par excellence. As Dr. Clifford Allbutt recently pointed out, the ministrations of the physician are directed not only to the relief of suffering humanity, but more minutely yet to the solace of the suffering man. There is, and inevitably must be, a personal bond of the closest description between the physician and his patient, and oftentimes the patient's family also. Dr. James J. Putnam, in his Shattuck lecture, said: "We can not really know the man whom we are called upon to treat without going far beyond his outward relations and penetrating in imagination deep into his mental life. 'The man' is, above all else, the mind of the man; and not only the mind as an organ of conscious thought, but the mind as an organ of bodily nutrition, and the mind as a vast theatre for the interplay of contending forces that do not always recognize the personal consciousness as their ruler. This is the man that the doctor should learn to know and treat. The need is not met by kindliness and humanity alone; the task is one for science also."

And Mr. W. J. Evans, in a paper on The Doctor, expressed this fact most happily when he said: "The humblest creature presents features which repay his scrutiny, and the proudest often traits which excite his pity. He is the confidant at their best and at their worst, and learns the guarded and unguarded truth relating to the mysteries of life. He reads the naked heart when it is either too weak or too sorrowful to hide its nakedness."

But not only is this close bond necessarily existent between the family physician and the patient; as I said before, it often binds him to the family also. On this point Beverley Robinson * has well said: "In the family relations, also, the chosen doctor who is to guide and direct, will be selected not because he knows everything pertaining to medical and surgical science, but because he among other men knows the most. If there are, as there must frequently be, occasions when the specialist's advice is sought for and required, he will stand by as the guardian of the family's first interests; he will be requested not to allow any narrow views to control the situation; not to permit any interference, medical or surgical, to be carried out unless with his entire approbation and indorsement. And the patients will select their physician because of his well-known, well-grounded intelligence, his previous long and honorable record of good and faithful work accomplished before his fellows and in the light of day—knowing as they will and must that he does for them not merely as he does for himself, but rather as he does for those he loves best in the world."

No man better than the physician can become the comforter of the sorrowful—more especially of those who suffer the more because they "have only themselves to blame." He can support the weak equally through those trials and adversities caused by sickness, and through those of worry, or remorse, or grief, which bid fair to result in it. The family physician, if he is a good physician, which means far more, mind you, than

* New York Medical Journal, August 12, 1899.
being a good medical craftsman, can help, as no one else can, the family in trouble over a wayward daughter or a scapegrace son.

If he is, as he ought to be, the trusted, tried, intimate family friend, he can be of the most material assistance in the training of youth—in the choice of a career for the son; in estimating the fitness of a life partner for the daughter. Nay, more! His tact and judgment may often serve to narrow a rift between those at the head of the family ere it widen into a chasm. To touch only lightly on a delicate subject, much comment has been aroused of late about the laxity of the marriage tie. It does not seem to be noted that it is infinitely more important to study with a view to removing the fundamental causes which are operative in leading to the tendency to break that tie than to spend time in railing at and devising obstacles to the operation of that tendency itself. Here is a grand field for the physician of the future. Let him study the question of the physiology and psychology of the marriage relation more thoroughly in all its three absolutely essential elements, intellectual, emotional, and physical; and then let him become in truth the adviser and confidant of his patients in regard to those all-essential matters which, whatever may be said to the contrary, do not adjust themselves naturally and as a matter of course in the majority of cases. They as often go wrong as right, if not oftener, unless the same attention is devoted to them as is given to producing the best results in any other natural operation. I say emphatically that at least one half of these driftings apart, which the moralists condemn as due to moral obliquity, are really due to purely natural psychological or physiological causes, which could either have been prevented by the trained physician's preliminary instruction in essential knowledge, or might have been obviated by his early intervention. Given the old-fashioned family physician, heart to heart and soul to soul with his patients, then no mock modesty or conventional cant need rob the young maiden or the young man of that necessary instruction to whose absence discordant matings, blighted affections, waning love, unhappy lives, inefficient parenthood, unresisted temptation, and final family disruption are principally due.

Man has a threefold nature—intellectual, emotional, physical. Companionship consists of a harmonious relation between two individuals in regard to one or more of these three elements. The "glorified companionship of matrimony" demands harmony in all of them. A certain variation is permissible—a certain excess on one side or deficiency on the other in any of these points, so long as it does not pass a certain limit. But, as in chemical affinities, so in matrimonial. Every union is only partial and unstable which leaves a valence, an affinity, unsatisfied.

(To be concluded.)

REPORT OF A CASE OF MEMBRANOUS DYSMENORRHEA.

By ROBERT E. COUGHLIN, M.D., BROOKLYN.

Skene says that "membranous dysmenorrhea occurs in single and married women—about as often in one class as the other"; while Croon says "the condition is peculiar to married women, although minute shreds are observed in single women." Hausmann adopted the view that these membranes are early abortions. Others state that membranous dysmenorrhea is merely an exaggeration of a normal process, and that the membrane is discharged in mass instead of in minute particles.

The current views regarding the affection are that it is due to inflammation, or else the result of gestation. Oldham and Skene discard these views and believe it would appear to be some derangement of innervation and nutrition.

Gynaecologists have given the subject special attention, and the literature of it is so extensive that Hart has said that "were its value equaled by its bulk, our knowledge of the subject would indeed be complete." It is easy to see that there is much difference of opinion on the aetiology and pathology of this rather rare affection.

As I have been unable to find any report of membranous dysmenorrhea occurring in the virgin, except the case reported in the Annales de la Société médico-chirurgicale de Liège, I believe the following case interesting in some respects:

Miss F., aged thirty-one years; occupation, laundress.

Family history negative, except that a sister died of pulmonary tuberculosis.

Previous History.—Patient has always been a healthy person. Had measles when a child. One year ago was attacked with influenza, which was followed by a bronchitis, which became more or less chronic in character.

Menstrual History.—Menstruation began at eleven; twenty-eight-day type. Pain present as a rule. Menstrual flow moderate in quantity.

Present Condition.—A large, bony young woman, well nourished and free from any neurotic manifestation. Physical examination shows the signs of an "apex catarrh" on the right side. Chest deep, with no signs of retraction in the infracavicular regions. Breasts large and firm.

History of Development and Course of Disease.—Eleven days ago menstruation began quite profusely. Some pain was present, but, as this generally occurred

* Since this was written my attention has been called to a report of a case published in the New York Medical Journal, vol. lxvii, page 298.
at such times, no particular attention was paid to it, and patient continued to perform her work of a laundress up to yesterday, when she was compelled to give up on account of the intense pain and the profuse hemorrhage. As time went on during the day the pain increased in severity, continued all night, causing complete loss of sleep until 6 A. M. to-day, when a mass was discharged per vaginam. This mass resembles very much the early decidua in every respect and, like it, is a triangular-shaped sac with three openings, rough and irregular on the outer surface, smooth on the interior.

Subsequent History.—After the discharge of the sac referred to Miss F. gradually became better; in a few days menstruation ceased and her recovery became complete. Up to the present time she has had no return of her trouble.

Treatment.—Sulphate of morrhine, a quarter of a grain, and atropine, one hundred-and-twenty-fifth of a grain, for the relief of the pain. Hayden’s viburnum compound and phenalgin were also administered. When patient began to convalesce tonic treatment was instituted.

It will be noticed that this patient was a well-nourished person, not neurotic, with no uterine disease or displacement, and giving a history of painful menstruation without the discharge of membrane previous to the attack referred to. It is also to be noticed that she was unmarried and that she has been free from any subsequent attacks.

The mass discharged, while a typical one, as described in many text-books on the subject, might easily be mistaken for the product of conception. Indeed, a number of my colleagues to whom I exhibited the specimen declared it to be the remains of an early abortion. As there can be no doubt in regard to the virginity of my patient it is easy to understand how one might err in giving an opinion from a medico-legal standpoint.

In reference to the slight chest trouble in this case, I do not believe it had any relation to the menstrual condition, as her nutrition was good and her health seemingly perfect.

Puerperal Fever Versus Antistreptococcic Serum.

By E. F. Brennan, M. D.

July 27th.—Mrs. G., a primipara, twenty years old, was twenty-four hours in labor under the care of a very unclean midwife who, being unsuccessful, decided to send for a physician. The patient was then delivered of her baby by means of forceps with a slight laceration of the perineum, which did not necessitate stitching.

After the expulsion of the placenta, which came away complete by abdominal expression, patient received a hot intra-uterine douche (mercury bichloride 1 to 5,000).

28th.—Condition of patient excellent. Temperature, pulse, and respiration normal.

29th.—Patient in excellent condition in the morning; had a slight chill in the evening.

30th, 10 A.M.—Temperature, 105° F.; pulse, 120; respiration, 30. Patient restless, skin hot and dry, marked nausea and vomiting.

5 P. M.—Temperature, 105° F.; pulse, 130; respiration, 35. Patient’s condition same, with the exception of fetid lochia and abdominal tenderness.

I then gave an intra-uterine douche of mercury bichloride, 1 to 5,000, and ordered vaginal douches of carbolic acid, 1 to 80, every four hours; also quinine sulphate, five grains; phenacetin, two grains; extract of aconite, a tenth of a grain, every three hours, without any effect.

31st, 10 A. M.—Temperature, 106° F.; pulse, 130; respiration, 35. Patient has an eruption of large blisters covering the breasts, buttocks, and face, containing a serous exudate. Lochia fetid; marked diarrhoea and general prostration. Medical treatment the same, with hot mercury bichloride douches, 1 to 5,000, every three hours, and a dry dressing of equal parts of zinc oxide, bismuth, and talcum applied to blisters after puncturing.

I also advised curettage as the only apparent means of saving the patient’s life, but no manner of argument would induce the husband of said patient to consent to operative measures, while perfectly satisfied to comply with any other method suggested.

August 1st, 2d, and 3d.—Temperature, 106° F.; pulse, 120 to 130; respiration, 30 to 35. Diarrhoea more marked and bloody. Patient refuses nourishment and is at times slightly delirious. Condition markedly septic. Spiritus frumenti, half an ounce; sulphate of quinine, five grains, every three hours. Intra-uterine douches twice daily. Vaginal douches, carbolic acid, 1 to 80, every three hours, and cold sponge baths. No improvement.

4th, 10 A. M.—Temperature, 104° F.; pulse, 120; respiration, 30. General condition fair. Sulphate of quinine, three grains; whisky, an ounce, every three hours. Nourishment for twenty-four hours consisted of milk, three pints: eggs, three.

5th (Ninth Day), 11 A. M.—Temperature, 106° F.; pulse, 125; respiration, 30. Lochia fetid and a marked increase of blisters (previously mentioned) over the posterior surface of the body. Antiseptic douches appear to have no beneficial effect.

3 P. M.—Antistreptococcic serum, ten cubic centimetres, injected (Parke, Davis & Co.). Temperature, 106° F.; pulse, 130; respiration, 35 at time of injection. Marked loss of flesh and strength.

6th, 10 A.M.—Temperature, 104° F.; pulse, 120; respiration, 25. Injected antistreptococcic serum, ten cubic centimetres. No increase in blisters. Slight salivation from douches of mercury bichloride, 1 to 5,000, but still continued their use.

4 P. M.—Temperature, 103° F.; pulse, 120; respiration, 30.

7th, 10 A. M.—Temperature, 101.4° F.; pulse, 120; respiration, 30. Injected antistreptococcic serum, ten cubic centimetres.

3 P. M.—Temperature, 105° F.; pulse, 120; respiration, 30. Diarrhoea bloody and with a gangrenous odor.

8th, 10 A. M.—Temperature, 101° F.; pulse, 100; respiration, 25. Injected antistreptococcic serum, ten cubic centimetres.

3 P. M.—Temperature, 100.4° F.; pulse, 110; respiration, 25. Internal medication and douches the same.
9th, 10 A.M.—Temperature, 99.5° F.; pulse, 90; respiration, 25. Marked loss of flesh, but condition good under the circumstances. Injected antistroptococcic serum, ten cubic centimetres.

4 P.M.—Temperature, 100° F.; pulse, 90; respiration, 25. Nourishment for twenty-four hours consisted of milk, two quarts; four eggs; whisky, eight ounces.

10th, 10 A.M.—Temperature, 100° F.; pulse, 90; respiration, 27. Lochia, slight odor. Blister drying up; very small ones of about the size of a pea occasionally showing. Carbolic douche, 1 to 80, morning and evening; in the interval, sterile saline solution douches, which appear to give patient great relief. Injected antistroptococcic serum, ten cubic centimetres.

11th, 10 A.M.—Temperature, 100° F.; pulse, 90; respiration, 25. When I saw the patient at this visit I concluded this sudden rise in temperature was due to the person in charge of patient having failed to douche her from 8 A.M. until 4 P.M.

Patient's general condition improved. Diarrhoea greatly lessened and free from blood. Nourishment retained for past twenty-four hours. Milk, two quarts; three eggs; whisky, six ounces. Sterilized saline douches every three hours.

12th, 10 A.M.—Temperature, 99.4° F.; pulse, 90; respiration, 27.

5 P.M.—Temperature, 99° F.; pulse, 85; respiration, 24. No diarrhoea; eruption completely cured. General condition much improved.

13th.—Temperature, pulse, and respiration normal.

14th.—Temperature, pulse, and respiration normal.

Patient in excellent condition, giving all manifestations of complete recovery.

\[265 \text{Alexander Avenue.}\]

Therapeutical Notes.

A Stomachic.—Riforma medica for September 7th gives the following:

R Hydrochloride of orxine ........... 30 grains;
Extract of gentian, 1 g.;
Powdered althaea root, 1 g. enough for 20 powders.
M. Divide into twenty powders and give from one to two daily in a cup of meat broth.

Leistikow’s Lotion for Pruritus of the Scrotum.—The Indépendance médicale for October 25th gives the formula as follows:

R Corrosive sublimate............. 3½ grains;
Alcohol ............. 375
Chamomile water, 1 g. each...
Chloroform ............. 5 drops;
Cherry-laurel water, enough to make

M. 1,500 grains.

The Treatment of Sore Nipples and Mastitis.—Dr. Rubeška (Archiv für Gynäkologie, Iviii, 1; Centralblatt für Gynäkologie, November 11th) has observed 1,244 cases of sore nipples among 3,152 nursing women in the Prague School for Midwives. His treatment consisted in the application of compresses wet with a three-per-cent. solution of boric acid and covered with gutta-percha tissue. In almost all the cases lactation was continued, the nipple being simply protected with a shield, and in seventy per cent. of them the trouble subsided within ten days. Only about one and a half per cent. led to the occurrence of mastitis. When that took place, the nipple was energetically disinfected, compresses wet with a half-per-cent. solution of corrosive sublimate were kept applied to it for two hours, the first milk was drawn by means of the breast pump, and an ice-bag was applied. If the inflammation began with a chill, high fever, and painful infiltration, he immediately injected two or three Pravaz syringe-gallons of a three-per-cent. solution of carbolic acid into the substance of the breast; if it began with less severity, this was not done unless the pain and fever continued on the second day. In only two cases thus treated did suppuration follow. No harm was done in any case, and the pain is described as not being great.

Capsules with Creosote.—Progrès médical for September 23rd ascribes the following to Mau Lange:

R Creosote, 1 g. of each ........... 1½ grain;
Powdered vegetable charcoal ....9 grains.
M.

An Ointment for Pruritus.—Progrès médical for September 23rd attributes the following to Leredde:

R Salicylate of methyl .......... 30 grains;
Oxide of zinc, 1 g. of each ....300
Vaseline, ............... 450
M.

For Alopecia.—Στατικὴ Προσώπου for October gives the following:

R Yellow precipitate of mercury. 30 grains;
Flowers of sulphur ............ 60
Oil of cade .................. 225
Vaseline .................. 450
M. For external application.

Lutaud’s Ointment for the Melasma of Pregnancy.—Riforma medica for November 10th gives the following formula:

R Oxide of zinc .......... 3 grains;
White precipitate .......... 1½ grain;
Cacao butter, 1 g. of each ....150 grains;
Castor oil, 1 g. of each ....10 drops.
Essence of roses ............. 10 drops.
M. The face to be anointed morning and evening.

Kaposi’s Ointment for Scabies.—Riforma medica for November 7th gives the formula as follows:

R Naphthol ....75 to 150 grains;
Alcohol .......... q. s.;
Vaseline ........... 1,500
M.

Sodium Vanadate as a Tonic.—The Indépendance médicale for October 18th gives the following formula:

R Sodium vanadate, 1 g. of each; 4 of a grain;
Sodium arsenate .......... 1 g. of a grain;
Sodium glycercophosphate 150 grains;
Gurus’s elixir (a French preparation of saffron and vanilla) ........... 4,500
M. S.: A dessertspoonful with each meal.

It is indicated in cases of anæmia, tuberculous disease, and diabetes. The effect of the arsenic is intensified and accelerated by the vanadium compound.
THE NEW YORK MEDICAL JOURNAL.
A Weekly Review of Medicine.
Published by
D. APPLETEN AND COMPANY.  Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, DECEMBER 9, 1899.

A PECULIAR HOSPITAL.
In the town of Niles, in Michigan, there is said to be an institution known as St. Luke’s Hospital. The Cleveland Journal of Medicine has been investigating some of the methods pursued by the hospital, and the results are set forth extensively in its November issue. Concerning the hospital itself, its resources and its internal management, nothing remarkable is stated, but one of the means by which it seeks to obtain funds and patronage is peculiar, to say the least.

A letter is written to some medical man informing him of the excellence of the hospital and the high character of its professional staff, of which he is invited to become a “member,” which he can do by remitting a certain sum of money—five dollars, we infer. His membership entitles him to send into the hospital for treatment any patient of his for whom hospital treatment may be desirable, and he is assured that he will receive a handsome percentage of the fees collected from such patient. He is informed that it is an “iron-clad rule” with the hospital never to appoint more than one physician in each place, and it is pointed out to him that his membership will be of great advantage to him in practice, inasmuch as he alone of his particular community will be in a position to afford patients the benefits of this remarkable institution; moreover, the hospital undertakes to inform the laity of his neighborhood that he has this advantage over his fellow-practitioners and to recommend him.

The hospital seems to be readily accessible by railway from an extensive region, and it is easy to see that, if a gudgeon can be found in each one of a large number of the towns contained in that area, the funds of the institution can be substantially enriched, but we have too much confidence in the common sense of the generality of medical practitioners to fear that this hospital and its questionable methods will meet with much encouragement, especially now that our Cleveland contemporaries have exposed them so plainly. It is true that the names of a few men of note in the profession have been paraded, and with some show of authority, as showing those men’s connection with this remarkable hospital, but, when its peculiar methods were pointed out to them, they have forbidden such further use of their names.

LEGISLATION FOR THE MEDICAL DEPARTMENT OF THE ARMY.
The surgeon-general of the army has favored us with the text of a bill which he will submit to Congress at this session. This bill is to increase the efficiency of the medical department both by increasing its size and by virtue of certain provisions which relate to the entrance of candidates into the corps. At present the medical department of the army has a total of one hundred and ninety-two medical officers. In addition to these there are at present in the service some four hundred civilian physicians serving under contract. The proposed bill will, if passed, authorize an increase of one hundred and twenty-four regular medical officers properly apportioned among the different grades. This increase is required both on account of the present necessities of the service and for future emergencies in case of war.

It is the policy of this government to depend for its armed force upon a regular army sufficient in size for the needs of peace and to act as a nucleus about which may be congregated the volunteer forces in time of war. This being the case, it is evident that the regular army in all its branches should be sufficient in numbers and efficiency to meet the requirements not only of a perfect organization in time of peace, but of expansion in time of necessity. With the advance of civilization and the consequent specialization of labor, the army, like all other branches of national life, has become highly specialized. The time is past when men could lay aside the implements of the workshop and the field and, congregating together, form effective fighting forces. The armies of to-day, from their size, their complexity of organization, and the multiplicity of detail necessary to their mobilization and support, require trained men and special means to insure their maintenance and efficiency. The military man, therefore, whether of line or staff, in any of its branches, is essentially a specialist, a specialist who has studied and who practises all means and methods toward the definite end of making an aggregation of men an effective offensive or defensive force. This being the case, the effectiveness of the force depends upon the efficiency of its directing or working units, and it can be efficient only in so far as those units are trained and capable of working together toward the definite end.

The medical department of the army is not alone
for the succor of the sick and wounded. This is one of its great functions, but its greater function is to maintain the fighting force at its highest efficiency by preventing, so far as possible, disability of the individual members of the force by sickness. It necessarily follows that the military surgeon is not only a medical and surgical practitioner, but a sanitary officer. And not only is he a physician, surgeon, and sanitarian, but an executive officer as well. The organization of a medical department requires divisions and subdivisions of authority by which its efficient working may be maintained. It follows that, however great the ability of a civil practitioner may be, he can not enter upon and immediately perform with efficiency the duties of a military medical officer. The questions of sanitation and hygiene which come up in the military service are peculiar and unlike those of civil life. The aggregation of large numbers of men in camp and field calls for special knowledge of hygiene and sanitation relative to conditions which the civil practitioner never meets with. Then, too, in time of war large general hospitals have to be established, which require for their efficiency a high order of executive and administrative ability on the part of the surgeons in command. Executive and administrative abilities of a high order are also called for in all the higher branches of the medical department, and these branches can not be properly administered except by men conversant with the complex methods incident to a highly specialized organization. For these reasons the medical department as an effective nucleus should not only be sufficient in size for the immediate working of a standing army, but large enough to be the directing force when volunteer forces are added until these latter forces can be trained to the proper point.

The number of officers in the medical department of the army is now so small that it barely sufficed for the needs of the army when on a peace basis, before the outbreak of the war with Spain, and was utterly inadequate in number to serve efficiently as a nucleus for organization when the army was increased. Now the increase in our coast defense has led to the establishment of eighteen posts in the Department of the East and ten on the Pacific coast, and a number of new posts have been established in the Hawaiian Islands and in Puerto Rico. To these are to be added a large number of stations, more or less permanent, in Cuba and in the Philippine Islands. The increase in number of the medical corps is therefore required, not only to meet the exigencies which now obtain in the service, but to provide a nucleus in case of future war.

The sections of the bill which relate to the appointment of candidates into the medical department provide for a probationary period of six months. During this probationary period the candidates are to attend the Army Medical School established in the city of Washington, and at the end of the prescribed period the faculty of the school will report to the secretary of war upon the fitness and relative standing of the probationary candidates. Those of the candidates who are recommended by the faculty will then be commissioned by the president to fill existing vacancies in the medical corps of the army. It is further provided that candidates who have rendered satisfactory service as acting assistant surgeons or as commissioned medical officers in the volunteer army of the United States for a period of six months or more shall be exempt from this period of probation. The reason for this provision for a probationary period is not only that the candidate may receive instruction in the duties of medical officers while at the Army Medical School, but that his fitness for a position in the medical department may be better determined than by the single brief examination which is all that is now required for entry into the corps.

It seems to us that the bill as presented is altogether wise and most necessary one, and we cordially recommend it to the approval and support of the profession at large. The medical department of the United States army is recruited from the profession throughout the country. In its ranks are representatives from all the leading medical colleges of the United States. For this reason it is in many respects a representative body, and the dignity and standing of the profession are affected either for good or for ill by the efficiency or inefficiency with which the medical department of the army performs its work. More than that, the efficiency of the medical department of the army is a matter of national importance, for the lives and welfare of the individual members of the army and the efficiency of the army as a whole depend in large degree upon the efficiency with which this department is administered and worked. We would therefore recommend all possible effort on the part of the profession to further the passage of the bill.

THE SKILLED WITNESS.

There has been much comment of late upon the admitted defects of our system of court procedure in the matter of "expert" testimony, particularly that of "experts" in medicine. We of the medical profession have freely acknowledged the shortcomings of physicians as skilled witnesses, but we have never really
felt that their weaknesses were due to either dishonesty or incompetency as a rule; we have rather imputed them to the faulty system under which skilled testimony is admitted by the courts. We are glad to see that much the same view of the matter is taken by Dr. William J. Herdman, of the University of Michigan, in a paper read by request at a meeting of the Association of Railway Claim Agents held on May 21st. Dr. Herdman shows convincingly, it seems to us, that the medical man who makes a poor show on the witness stand is not necessarily either a hired perjuror or an ignoramus, and he makes it evident that a well-informed and well-meaning physician may so fail to comprehend the real and essential purport of the questions put to him, or so fail to be adequately understood by the court officers, as to make his testimony, although given in all truth and fairness, seem open to severe criticism.

Dr. Herdman appears to look with favor upon some such remedy for all this as is supposed to be embodied in propositions that have been submitted to the legislatures of New York, Pennsylvania, and Illinois, but have thus far not been enacted as statutes. The essence of these propositions is that an official body of medical "experts" should be appointed by the courts or by the medical societies, and that they alone should be held competent to give skilled testimony. The same opinion has been expressed by a number of medical organizations, but we believe the scheme to be a delusion. It is in force in certain European countries, but it does not seem to give invariable satisfaction. This is not a journal of law, and we do not feel entitled to express an opinion on a legal question, but we have the impression that each party to an action at law is at liberty to produce such witnesses as it may choose, whether as to matters of fact or as to matters of opinion, and that it is the privilege of each party to cross-question all witnesses. We should like, however, to see the monstrosity known as the hypothetical question frowned down upon by the courts, and we take it that that is Dr. Herdman's desire, too. Still more we should like to see the lawyer's harangue, concealed under a question, stifled by the courts. A witness is not a criminal to be tortured, and that proposition ought to be admitted by judges.

AN OBJECT LESSON IN VACCINATION VERSUS SMALL-POX.

As is well known, small-pox is endemic in most Spanish-American countries. In December, 1898, small-pox was prevailing in Puerto Rico to such an extent that in January, 1899, the reports of post surgeons in sixteen out of the seventy-one municipalities showed three thousand cases of small-pox as having occurred in the previous two months. The governor-general on January 27, 1899, by General Order No. 7, ordained that "every resident who has not had this disease will be vaccinated, and hereafter all infants must be vaccinated before reaching the age of six months." Surgeon-Major Groff, director of vaccination in Puerto Rico (Medical News, November 25th), describes the government measures for the carrying out of this provision, which appear to have been extraordinarily well conceived and completely executed. A government vaccine farm was established, and by June 30th, when the work was closed, some 790,000 persons had been vaccinated, vaccine having been distributed to physicians free of cost. In view of the many difficulties encountered, the greatest credit reflects on the administration. As to results, Major Groff reports, "not a single death which could be strictly attributed to the vaccination occurred. There were some infected arms, and some of the people and a number of the municipalities asked for relief because the poor were not able to perform their accustomed labors, but this trouble was not serious. Not a single riot or lesser disturbance occurred. The people generally welcomed the operators." The total cost amounted to $32,000, or about four cents a head. Finally, Major Groff says: "At this date, October 20th, not a single case of small-pox is known to either the military or the civil authorities" (the italics are ours), "and it may be considered stamped out of Puerto Rico." And yet there are otherwise sensible people who denounce vaccination as, if not entirely useless, at least dangerous out of all proportion to the benefits conferred.

THE UNSCRUPULOUS PRESCRIPTION OF ENSLAVING DRUGS.

The Canadian Pharmaceutical Journal for November comments editorially under the simple heading "Criminal" upon a case occurring in a Canadian city in which a lady applied to a druggist for one ounce of cocaine. Finally the lady asked for one ounce of a six-per-cent. solution of cocaine. This, as also the former order, was refused, on the druggist finding that the lady wanted the drug for her son to take. Further inquiry elicited the facts that she had had no previous difficulty in getting her demands complied with, and that one of the leading physicians of the city had "said that it was all right to take it so long as the quantity was limited and the time" (occasion?) "not too frequent." Upon this the Canadian Journal comments as follows: "This lady's story was almost incredible, and yet her veracity was and is unquestionable; assuming it true, then a term in the penitentiary at stone-breaking would be none too severe a punishment for a doctor or a druggist who would aid a young life on the road to perdition for the paltry dollars which would be made from feeding the soul-destroying appetite." For the credit both of the medical and pharmaceutical professions, we can only say that we trust that there is some misapprehension of facts. Failing that, our own opinion is best conveyed by a hearty indorsement of the Journal's laconic heading, "Criminal!"

AN ANTIVIVISECTION STORY.

The title of a short story by Elizabeth Stuart Phelps, recently published by Messrs. Houghton, Mifflin, & Co., is Loneliness, which is the name given by a little girl to her pet dog. The dog is stolen, and its loss is

 får

A PERSISTENT FLOW OF CEREBRO-SPINAL FLUID.

A somewhat remarkable case is that related by Dr. A. Lacae (Berliner klinische Wochenschrift, 1899, No. 40; Wiener klinische Rundschau, November 5th). A schoolboy, seventeen years old, was attacked with caries of the mastoid process of the temporal bone. An operation was undertaken for the removal of the diseased bone, and the dura and the arachnoid were found to have been perforated. Through the perforation there was such an abundant flow of cerebro-spinal fluid that, beyond the removal of a sequestum, further operative procedures were abandoned. The flow continued for five weeks, in great abundance for the first two weeks, yet at no time were any cerebral symptoms present, and there was no fever or any disturbance of the pulse.

THE BUBONIC INFECTION OF PARAGUAY.

In view of the prevalence of the Oriental plague, a disease closely resembling it, said to prevail in Paraguay, becomes of interest. Dr. Diogene Decoud (Semana Médica, September 4th; Independencia medica, November 1st) describes an outbreak that occurred recently in which twenty-three out of three hundred and fifty soldiers were attacked in the course of three weeks. The disease begins suddenly with great prostration and high fever, and in from three to six hours the buboes are perceptible. They grow rapidly, reaching the size of a fist in a day or two. They are generally seated in the left groin, but sometimes in the right, and once the author has seen one in the axilla. They are exquisitely sensitive, but there is little involvement of the skin, and they usually terminate by resolution. During the period of full development of the disease the tongue is covered with a moist yellowish coat. Except slight congestion of the bases, there are no pulmonary signs, and there is no disturbance of the heart. In cases about to end fatally the abdomen is tympanitic, but painless. The author observed no diarrhoea; on the contrary, there was constipation. During the height of the disease the patient is apathetic. In the grave cases there is mild delirium with agitation and with occasional sudden movements that result in the patient’s falling out of bed. As the fatal issue approaches, the pulse falls suddenly and then is accelerated.

LATENT ABSCESS OF THE PROSTATE.

At the recent French Congress of Urology (Indépendance médicale, November 1st) Dr. Desnos called attention to two forms of prostatic abscess to which the classical descriptions of symptoms would not apply. In the first form, of which he had seen two cases, an abscess of considerable size, large enough to cause retention of urine, formed in the course of prostatic hypertrophy, but without fever or other signs of suppuration. In the other form, of more frequent occurrence, small abscesses formed in the course of hemorrhagic prostatitis and burst into the urethra.

ILLEGAL PRACTICE IN THE COUNTY OF NEW YORK.

The Medical Society of the County of New York deserves great praise for its assiduity in detecting and punishing offenders against the medical-practise law. According to a report recently furnished to us by the secretary, Dr. William E. Ballard, from May to October, 1895, seventeen prosecutions were brought by the society, with ten convictions; from October, 1895, to October, 1896, fifty-six prosecutions, with thirty-six convictions; from October, 1896, to October, 1897, fifty-one prosecutions, with thirty convictions; from October, 1897, to October, 1898, thirty-seven prosecutions, with twenty-three convictions; from October, 1898, to October, 1899, forty-five prosecutions, with thirty-three convictions.

A CHECK TO SUBSTITUTION.

We congratulate the firm of Fairchild Brothers & Foster on the successful issue of their suit to restrain an apothecary from repeating his offense of substituting some other preparation for their "essence of pepper," theirs being specified. The defendant has to pay the costs, amounting, it is said, to about $500. It is to be hoped that this United States circuit court decision will act as a check on the wretched practice of substitution.

LEPROSY IN GUAM.

It seems that there are lepers in Guam, and that an officer of the navy who recently visited the island has recommended their removal to the Hawaiian leper settlement. This step may be found advisable, but as a rule, we think, a community should take care of its own lepers.

THE TREATMENT OF THE SUPPURATIVE STAGE OF SMALL-POX BY VACCINATION.

Vaccination during an attack of small-pox is not generally credited with any advantages. According to the Riforma medica for November 15th, however, Kotowschikoff (Zeitschrift für klinische Medizin, xxxviii, 1-3, 1899), as the result of his own experience, as well as that of others, considers vaccination the best treatment for the suppurative stage of this disease. Incubations of vaccine, repeated twice daily, have, says the author, a very great therapeutic effect, not only in the prodromal stage, but in the initial stage also. Daily incubations begin on the first and second days after the appearance of the eruption, even in grave cases of the disease, cause the suppurative stage to pass through a milder course. The author, indeed, extends this practice to the third day, being convinced that even at this late period it influences its course favorably.

ITEMS.

A Bill for the Relief of Assistant Surgeons with the Rank of Captain in the Volunteer Army of the United States.—The following bill has been prepared by the surgeon-general and approved by the secretary of war:
ITEMS.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That assistant surgeons in the volunteer army of the United States commissioned by the president as captains, in accordance with the provisions of an act for increasing the efficiency of the army of the United States and for other purposes (approved March 2, 1899), are entitled to the pay of a "captain mounted" from the date of their acceptance of such commission as prescribed by law.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported for the two weeks ending December 2, 1899:

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending December 1, 1899:

**Small-pox—United States**
- Cairo, Ill. Nov. 30. 3 cases.
- New Orleans, La. Nov. 18-25. 6 cases.
- Cleveland, Ohio. Nov. 18-25. 8 cases.
- Nashville, Tenn. Nov. 18-25. 3 cases.
- Portsmouth, Va. Nov. 18-25. 2 cases.

**Small-pox—Foreign**
- Antwerp, Belgium. Oct. 28-Nov. 4. 7 cases.
- Prague, Bohemia, Austria. Oct. 28-Nov. 4. 7 cases.
- Ontario, Canada. Nov. 10. 20 cases.
- Quebec, Canada. Aug. 21-Nov. 27. 138 cases.

**All in Kamnowarska County.**
- City of Mexico, Mexico. Oct. 29-Nov. 5. 5 cases.
- Vera Cruz, Mexico. Nov. 6-24. 2 cases.
- Moscow, Russia. Oct. 22-28. 2 cases.
- Odessa, Russia. Oct. 23-Nov. 4. 1 case.
- Warsaw, Russia. Oct. 25-Nov. 4. 7 cases.
- Constantinople, Turkey. Oct. 25-Nov. 6. 1 case.

**Yellow Fever—Foreign.**
- Rio de Janeiro, Brazil. Oct. 12-30. 3 cases.
- Havana, Cuba. Nov. 16-23. 10 cases.
- Puerto Principe, Cuba. Nov. 18. 1 case (soldier).
- Vera Cruz, Mexico. Nov. 8-24. 3 cases.

**Cholera.**

**Plague—Foreign.**
- Alexandria, Egypt. Nov. 6. 1 case.
- Cadiz, Spain. Nov. 27. 1 case (suspected).

**The Death of Dr. Henry Hodden Mudd, of St. Louis,** is announced to have occurred on November 20th, in the fifty-fifth year of his age. Dr. Mudd was one of the most prominent and esteemed medical men of St. Louis, and his death will be widely felt as a bereavement to the profession and to the community.

**A Bill for the Relief of Acting Assistant Surgeons in the United States Army.**—The following bill has been prepared by the surgeon-general and approved by the secretary of war:

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled:

**Section 1.** That on and after the passage of this act acting assistant surgeons in the army of the United States shall have the same rights and privileges as regards leaves of absence as commissioned officers of the army.

**Section 2.** Acting assistant surgeons in the army of the United States who have been appointed since the first day of May, 1898, who have been absent from duty, by proper authority, on account of sickness contracted in the service shall be paid for the time of such absence at the rate per month specified in their contracts.

**A Bill for the Increase of the Medical Department of the Army.**—The following bill has been prepared by the surgeon-general and approved by the secretary of war:

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled:

**Section 1.** That there shall be added to the number of medical officers of the army now authorized by law four assistant surgeons-general with the rank of colonel, ten deputy surgeons-general with the rank of lieutenant-colonel, thirty surgeons with the rank of major, and eighty assistant surgeons with the rank of first lieutenant who shall have the rank of captain at the expiration of five years' service, as now provided by law. Provided that the original vacancies created by this act in the grade of colonel, lieutenant-colonel, and major shall be filled by seniority promotion in accordance with established laws and regulations.

**Section 2.** Hereafter candidates for appointment in the medical corps of the army, who pass a medical examining board in compliance with existing regulations, shall be appointed acting assistant surgeons for a probationary period of six months; during this probationary period they shall attend the Army Medical School established at the Army Medical Museum in the city of Washington, and the faculty of the Army Medical School shall report to the secretary of war at the end of the prescribed course of instruction upon the fitness and relative standing of the probationary candidates; those who are recommended by the faculty may then be commissioned by the president to fill existing vacancies in the medical corps of the army.

**Section 3.** Acting assistant surgeons appointed in accordance with the provisions of Section 2 shall not exceed the number of vacancies existing or to result from retirements during the probationary period.

**Section 4.** The number of acting assistant surgeons appointed in accordance with the provisions of Section 2 shall not exceed the number of vacancies existing or to result from retirements during the probationary period.

**Section 5.** Candidates who have rendered satisfactory service as acting assistant surgeons or as commissioned medical officers in the volunteer army of the United States for a period of six months or more shall be exempted from this period of probation and may be
commissioned at once if vacancies exist and they pass a satisfactory examination as to their physical, moral, and professional qualifications.

The Association of Acting Assistant Surgeons of the Spanish War was organized in New York on Tuesday, December 5th. Dr. Axel Ames, of Massachusetts, was chosen to be president.

The Practitioner’s Society of Dallas, Texas, was organized at the Hermitage Hospital on December 1st, and the following officers were elected: President, Dr. Lawrence Ashton; vice-president, Dr. J. B. Titterington; secretary, Dr. C. L. Johnson. The next meeting will be held at the residence of the president on Monday, December 18th.

The Randall’s Island Hospitals and Asylums.—Dr. E. L. Cooks has been appointed attending dermatologist to these institutions.

The German Hospital in Brooklyn, Eastern District, was opened with suitable ceremonies on Monday, December 4th.

The St. Louis Medical Society.—At the last regular meeting, on Saturday evening, the 2d inst., Dr. R. B. H. Gradwohl read a paper entitled Epidemic Cerebrospinal Meningitis; a Clinical and Bacteriological Study of Thirty-Four Cases.

The Buffalo Academy of Medicine.—At the last quarterly meeting, on Tuesday evening, the 5th inst., the programme for the Section in Surgery was as follows: The Value of Normal Salt Solution in Surgery, with Abstracts of Cases, by Dr. Chauncey P. Smith; Hypertrophy of the Prostate, by Dr. C. F. Durand; and Desiccated Suprarenal Capsule in Acute Coryza, by Dr. Frederick II. Millener.

Changes of Address.—Dr. H. I. Birkenhauser, to No. 216 East Seventeenth Street, New York; Dr. W. V. Richtmire, to No. 322 East Nineteenth Street, New York.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 25 to December 2, 1899:

BATHE, Thomas W., Acting Assistant Surgeon, United States Army, having returned to San Francisco, will report at the United States General Hospital, the Presidio.

De Witt, Calvin, Lieutenant-Colonel and Deputy Surgeon-General, United States Army, is relieved from the command of the Josiah Simpson General Hospital, Fort Monroe, Virginia, and O'Reilly, Robert M., Major and Surgeon, United States Army, will take charge of that hospital.

James, William F., Acting Assistant Surgeon, United States Army, is assigned to duty on board the transport Wysefield, during the voyage of that vessel to the Philippine Islands.

Molony, Louis A., Acting Assistant Surgeon, United States Army, is assigned to duty at the United States General Hospital, Presidio of San Francisco.

Winne, C. K., Major and Surgeon, United States Army, is granted leave of absence for thirty days.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending December 2, 1899:

Beebe, D. G., Assistant Surgeon. The order of October 14th, detaching him from the Bennington and ordering him to the Ranger, is revoked.

Davis, E., Assistant Surgeon. Appointed assistant surgeon, November 21, 1899.

Lumsden, G. P., Surgeon. Ordered to temporary duty on the Franklin during the leave of absence of Guthrie, J. A., Passed Assistant Surgeon; thence home to await orders.

Stoughton, J., Passed Assistant Surgeon. The order of October 14th, detaching him from the Monadnock and ordering him to the Bennington, is revoked.

Taylor, J. S., Assistant Surgeon. Detached from the Independence and ordered to the Scindia.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending November 30, 1899:

Peckham, C. T., Surgeon. Granted leave of absence for four days.

Glennan, A. H., Surgeon. Relieved from duty as quarantine officer at the port of San Juan, Puerto Rico, and directed to proceed to New Orleans and assume command of the service.

Pettus, W. J., Surgeon. Relieved from duty at the Cape Charles Quarantine Station and directed to proceed to Cleveland and assume command of the service.

Smith, A. C., Passed Assistant Surgeon. Relieved from duty at Norfolk, Virginia, and directed to report at Washington for special temporary duty.

Stimpson, W. G., Passed Assistant Surgeon. To rejoin station at St. Louis.

Eager, J. M., Passed Assistant Surgeon. Relieved from duty at Detroit and directed to proceed to Cincinnati and assume command of the service.

Oakley, J. H., Passed Assistant Surgeon. Relieved from duty at Evansville, Indiana, and directed to report at Washington for special temporary duty.

Sprague, E. K., Passed Assistant Surgeon. Relieved from duty in the Hygienic Laboratory, Washington, and directed to proceed to New York and report to Surgeon L. L. Williams (Immigration Depot) for special temporary duty.

Thomas, A. R., Passed Assistant Surgeon. Relieved from duty at the Reed Island Quarantine Station and directed to report at Washington for special temporary duty.

Wickes, H. W., Passed Assistant Surgeon. Relieved from duty at Cleveland and directed to report at Washington for special temporary duty.

Greene, J. B., Passed Assistant Surgeon. To report at Washington for special temporary duty. To rejoin station at Boston.

Matthewson, H. S., Assistant Surgeon. Relieved from duty at the San Francisco Quarantine Station and directed to report at Washington for special temporary duty.

Lavinder, C. H., Assistant Surgeon. Relieved from duty as quarantine officer at the port of Ponce,
Puerto Rico, and detailed as quarantine officer at San Juan, Puerto Rico.

GRUBBS, S. B., Assistant Surgeon. Relieved from duty as quarantine officer at the port of Cienfuegos, Cuba, and directed to report at Washington for special temporary duty.

RUSSELL, H. C., Assistant Surgeon. Relieved from duty at Cairo, Illinois, and directed to proceed to Boston for duty and assignment to quarters.

VON EDENDE, R. H., Assistant Surgeon. To rejoin station at New Orleans.

FRICKS, L. C., Assistant Surgeon. To report at Washing-}

gton for special temporary duty.

RICHARDSON, T. F., Assistant Surgeon. Relieved from duty as quarantine officer at the port of Nu-civas, Cuba, and directed to proceed to the Reedy Island Quarantine Station and assume command of the service.

KING, W. W., Assistant Surgeon. Relieved from duty at New Orleans and assigned to duty as quarantine officer at Ponce, Puerto Rico.

KORN, W. A., Assistant Surgeon. Relieved from duty at Chicago and directed to proceed to Evansville, Indiana, and assume command of the service.

HOULT, J. M., Assistant Surgeon. Relieved from duty at St. Louis and directed to proceed to Cairo, Illinois, and assume command of the service.

EDSON, ELMER R., Assistant Surgeon. To proceed to St. Louis for duty and assignment to quarters.

WILLE, CLARENCE W., Assistant Surgeon. To proceed to Boston for duty and assignment to quarters.

AMESSE, JOHN W., Assistant Surgeon. To proceed to Detroit for duty and assignment to quarters.

WILSON, ROBERT L., Assistant Surgeon. To proceed to San Francisco for duty and assignment to quarters.

BROWN, B. J., Jr., Acting Assistant Surgeon. Granted leave of absence for three days.

FRICK, JOHN, Acting Assistant Surgeon. Relieved from duty at Santiago, Cuba, and directed to proceed to Havana, Cuba, for duty.

LINDSLEY, J. M., Acting Assistant Surgeon. Detailed as quarantine officer at the port of Cienfuegos, Cuba.

STONE, OWEN W., Acting Assistant Surgeon. Detailed as quarantine officer at the port of Nu-civas, Cuba.

Appointments.

EDSON, ELMER R., of Indiana; WILLE, CLARENCE W., of Pennsylvania; AMESSE, JOHN W., of Michigan, and WILSON, ROBERT L., of Texas, commissioned as assistant surgeons.

Society Meetings for the Coming Week:

MondA_y, December 11th: New York Academy of Medicine (Section in General Surgery); New York Academy of Sciences (Section in Chemistry and Technology); New York Medico-historical Society (private); New York Ophthalmological Society (private); Lenox Medical and Surgical Society, New York (private); Harlem Medical Association of the City of New York; Gynecological Society of Boston; Burlington, Vermont, Medical and Surgical Club; Norwalk, Connecticut, Medical Society (private).

Tuesday, December 12th: New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private); New York Obstetrical Society (private); Buffalo Academy of Medicine (Section in Medicine); Kings County, New York, Medical Association; Rome, New York, Medical Society; Medical Society of the County of Rensselaer, New York; Newark (private) and Trenton, New Jersey, Medical Associations; Clinical Society of the Elizabeth, New Jersey, General Hospital and Dispensary; Northwestern Medical Society of Philadelphia; Practitioners' Club, Richmond, Kentucky; Richmond, Virginia, Academy of Medicine and Surgery.

Wednesday, December 13th: New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Society of the Alumni of the City (Charity) Hospital; Society for Medical Progress, New York; Pittsfield, Massachusetts, Medical Association (private); Philadelphia County Medical Society.

Thursday, December 14th: Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; Medical Society of the County of Cayuga, New York (semiannual); South Boston, Massachusetts, Medical Club (private); Pathological Society of Philadelphia.

Friday, December 15th: New York Academy of Medicine (Section in Orthopedic Surgery); Clinical Society of the New York Post-graduate Medical School and Hospital; Baltimore Clinical Society; Chicago Gynecological Society.

Births, Marriages, and Deaths.

Married.

BURRITT—DRUMMOND.—In St. Louis, on Wednesday, November 29th, Dr. William H. Burritt, of Huntsville, Alabama, and Mrs. Josephine H. Drummond.

CHILD—MCGRAW.—In New York, on Tuesday, November 28th, Dr. Albert Ewing Childs and Miss Amelia McGraw.

GIBBS—HOBBY.—In Iowa City, Iowa, on Monday, October 16th, Lieutenant G. S. Gibbs, Jr., United States Signal Corps, and Miss Ruth A. Hobby, daughter of Dr. C. M. Hobby.

HINCKLEY—CHANCE.—In Chicago, on Wednesday, November 22d, Dr. Hugh Hinckley, of New Orleans, and Miss Mae Louise Chance.

LIBBY—WEDDELL.—In Nashua, New Hampshire, on Wednesday, November 22d, Dr. Charles Emerson Libby and Miss Nellie Parker Weddell.

ROBIN—TITUS.—In New Orleans, on Wednesday, November 29th, Dr. Ernest Alexis Robin and Miss Mary Titus.

SCHAEFFER—NAUNIT.—In Brooklyn, on Monday, November 27th, Dr. Joseph William Schaeffer and Miss May Jordan Naunit.

SHEPARD—GROSVENOR.—In Athens, Ohio, on Monday, November 27th, Dr. O. M. Shepard, of Columbus, Ohio, and Miss Grace Grosvenor.

TUCKER—DERBY.—In New York, on Tuesday, November 28th, Professor Samuel A. Tucker and Miss Anne Caroline Derby, daughter of Dr. Richard H. Derby.
Letters to the Editor.

THE ETIOLOGY OF BERIBERI.

BUFFALO, N. Y., November 29, 1899.

To the Editor of the New York Medical Journal:

Sir: Because "Dr. Takaki's Japanese theory that rice produces kakke . . . does not hold water" (see p. 789, New York Medical Journal, November 25th), allow me to refer to an article of Dr. K. Yamagiva, professor at the Imperial University at Tokio, in Virehov's Archiv, Band elvi, 1899. He calls attention to the chief pathologic-anatomical changes: 1. Dilatation and hypertrophy of the right and left ventricles, with fatty degeneration of the heart muscle. 2. Degeneration of the peripheric nerves. 3. Atrophy and degeneration of the muscles. 4. Parenchymatous degeneration of the kidneys. 5. Dropsy. Dr. Yamagiva explains the changes by a hypothetical poison which, either through direct influence on the walls of the vessels or through influence on the nerves of the vessels causes contraction of the smallest arteries. This increases the resistance in the periphery of the pulmonary and general circulation, with consecutive changes of the heart, the result of which is a bad nutrition of the organs and tissues with regressive changes. He believes that this poison is brought into the body preformed. He uses the same arguments as the other adherents of the intoxication theory have used, and also some new ones—i. e., that the beriberi in infants subsides promptly when the sick mother stops nursing; that, as in other intoxications, a central scotoma is often found; and that in a certain state of the disease laxatives have often a very favorable influence on its course. He thinks that the poison arises from a certain sort of rice badly preserved. "Kakke oder Beri-Beri bedeutet nach meiner Auffassung eine durch den täglichen Gebrauch einer schlecht aufbewahrten Sorten von gekochtem Reis als Hauptnahrung entstehende Intoxication-Krankheit."

The clinical picture described by Dr. Ashmead of beriberi is somewhat mysterious—i. e., "We must consider that the respiration of the beriberi patient is necessarily abdominal." I thought that one half part of the human race had an abdominal respiration, and the other had a costo-abdominal.

The logical conclusion of the sentence "Insufficiency of alimentation can not be the cause of beriberi, because there is no deficiency of red corpuscles in beriberi blood," goes too far for me. I doubt the statement. Mephistopheles said: "Blut ist ein ganz besonderer Saft." And I think we do not know enough about the composition of the blood to give us the right to draw far-reaching inferences.

I do not know whether Dr. Yamagiva will be made a nobleman.

E. E. Blaauw, M. D.

ATROPINE IN DISEASE OF THE EYE.

KANSAS CITY, Mo., November 25, 1899.

To the Editor of the New York Medical Journal:

Sir: In your journal for November 18th you quote Dr. Edward Jackson, of Denver, as suggesting that physicians should never use atropine in conjunctivitis. This, in my opinion, is not good advice for the physician who is not expert at making a diagnosis, to whom Dr. Jackson evidently refers. He says that much harm is sometimes done by the use of atropine, but says nothing about the eyes that have been lost because atropine had not been used.

In the November number of the Western Medical Journal, in an article on the importance of dilating the pupil in treating diseases of the eye, I state that four patients have recently come under my observation each of whom had lost an eye because atropine had not been used.

I also state that if atropine were used in all eye diseases more eyes would be saved than if it were not used in any of them.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

BY ARTHUR N. TAYLOR, LL. B.

XLVIII.

PRIVILEGED COMMUNICATIONS.

(Continued from page 791.)

Rule Applies to Knowledge Regarding Testamentary Capacity.—There are certain classes of cases to which the applicability of the statutes scaling the lips of the physician regarding information gained in his professional capacity have been or are seriously questioned.

At an early date it was thought that the statutes enjoining secrecy upon physicians could not have been intended to apply to testamentary cases. Justice Bradford, in 1850, after a somewhat extended examination of the question, expressed it as his opinion that he did not think they were within the reason or the intention of the statute.* As late as 1883 this opinion was cited with approval and followed in the surrogate court; but in 1886 the court of appeals of New York repudiated

* Allen vs. Public Administrator, 1 Bradf., 221.
† Whelpley vs. Loder, 1 Demarest, 368.
the distinction between testamentary cases and those of the ordinary sort. Justice Earl, in delivering the opinion of the court, logically said: "But it is claimed that the statute should be held not to apply to testamentary cases. There is just as much reason for applying it to such cases as to any other, and the broad and sweeping language of the two sections cannot be so limited as to exclude such cases from their operation. There is no more reason for allowing the secret ailments of a patient to be brought to light in a contest over his will than there is for exposing them in any other case where they become the legitimate subject of inquiry." This decision has been followed by an almost unbroken line of decisions in several of the States having such statutes, so that it may now be stated with reasonable certainty that the knowledge of a physician gained from a professional relation with his patients is protected as fully in testamentary cases as in those of any other sort. There has, however, in New York been a desire shown to relax from the liberal and broad interpretation of the law by permitting the physician to be asked whether or not the information acquired by him, which is desired to be shown in the case, was necessary to enable him to act in his professional capacity, and, upon his answering this question in the negative, to permit him to disclose such information.

The privilege which prevents the physician from disclosing all information gained in the course of his professional intercourse is one which may be waived by the patient, and it has been very properly held that, where the patient requests the physician to place his name upon the patient's will as subscribing witness, he thereby waives the privilege and invites a full and proper examination of the matters and facts as to which the physician's lips would otherwise have been sealed.

**Regarding Inquisition of Lunacy.**—The question whether or not a regular attending physician is competent in an inquisition of lunacy to testify regarding his patient's condition is one upon which there does not seem to be a clear issue, as the opposition of two courts has been sub judice. Judge Werner was of the opinion that the statute did not disqualify the physician; he said: "I do not think the section applies to a proceeding of this character. No physician can be better qualified to testify to the sanity or insanity of a person than he who has for some time attended such person in a professional capacity." The latter part of this proposition is undoubtedly correct, yet the same statement may be made with equal force in case of the contest of a will upon the ground of a want of testamentary capacity on the part of the testator; and, yet we have just seen that the law applies in such cases. Until this question is settled by a more authoritative decision it may well be considered in doubt.

**Application in Criminal Cases.**—It has been observed that by the express limitation contained in the

PITH OF CURRENT LITERATURE.

The Medicinal Treatment of Uterine Cancer.—Dr. Thomas More Madden (British Medical Journal, October 14th) refers to celandine, or swallowwort, as a very old remedy which has been again recently reintroduced into practice in the treatment of cancer cases, and says that it was employed in some cases of malignant disease of the uterus in his wards. In three of these in which the celandine extract was locally applied and administered internally, the condition of the cancerous ulceration was rapidly and distinctly improved for a time, in two no change was produced, but in none of them was any permanent curative effect produced. The local injections of absolute alcohol, as recommended by Schultz, were employed in some of his inoperable cases of cervical cancer. In none of these the first injection of alcohol was followed by such local pain and constitutional disturbance as to prevent its repetition. In two other cases similar but deeper parenchymatous injections, repeated at intervals of two or three days, were attended with some diminution in the amount and force of the discharge, and apparent shrinkage in the diseased structure. In neither of these cases, however, did the patient remain sufficiently long under observation to warrant any conclusion as to the probable duration of these effects. Several years ago Dr. Madden called attention to the value of methylene blue as a local analgetic in

* Sullings vs. Shakespeare, 46 Mich., 413.
pruritus and other gynecological cases, and since then he has frequently employed it in this way and to relieve the pain of uterine cancer. In cases of inoperable cervical carcinoma, a pledget of sterilized gauze saturated in a five-per-cent. solution of methylene blue will occasionally not only allay pain, but also cleanse and temporarily improve the condition of the parts, while the injection of a similar solution by the needle into the substance of a medullary growth may for a time cause some diminution of its size and abatement in the amount and factor of the discharge.

The Therapeutic Value of Alcohol.—At the New York State Medical Association Dr. Thomas J. Hillis (Medical News, November 4th) said that until recently we had very little definite information as to the medical properties of alcohol. There had been a good deal of talk, mostly coming from those who were fanatically opposed to its use, and every good effect had been deni ed to it. Some even went so far as to say that it was not a stimulant. Not long ago Professor Atwater showed that it was used by the system as a food. There was no doubt that in various allotropic modifications which it underwent in the chemical laboratory of the body it developed many other properties beyond that of stimulation. It was a tonic, heat-producing food of the most valuable kind. It had been abused and would be abused, but the abuse of a thing could not logically be argued against the proper use of it.

It was in conditions of fatigue particularly that alcohol was of special service. It was much better than coffee and produced its effect more rapidly. When great fatigue existed it was promptly burned up in the body and did not produce its ordinary intoxicating effect. Under these conditions from eight to ten ounces of it even might be taken and produce only slight stimulation. Like shavings in a furnace, it was burned up by the fire of muscular metabolism. Much of the abuse of alcohol by the medical profession had come from the fact that it had been given too early or too late in the course of a disease, or that too much or too little of it had been given. Its administration must not be left to the nurse, but must be assumed by the doctor himself. It must be regulated not according to any fixed rule, but according to the effect produced upon the patient.

The primary factor in the matter was the stomach. If the stomach took food well, then alcohol was not needed; but when food could not be taken, alcohol was of the greatest service. Especially it must never be given if it disturbed the stomach. One day it might be poison in a given case and the next day it might do good. Alcohol should never be taken at the beginning of a journey, for it lowered the temperature and increased the tendency to fatigue. At the end of a journey it was usually of very great service. At the beginning of diseases that were accompanied by excitement it would do harm. In exhausted conditions of the patient, especially when nutriment was not taken well, it was of the greatest service. It acted in four minutes, while beef tea required twenty to act and was not as efficient. Alcohol should never be taken immediately after meals, for it paralyzed the digestive ferment, coagulated the albuminoids, relaxed the walls of the stomach, and might stop the process of digestion entirely. Three hours after digestion, especially if the fatty acids were present, causing the condition known as pyrosis, alcohol would neutralize the fatty acids, stimulate the peristaltic action of the stomach, and get rid of the uncomfortable feeling. Dr. Didama and Dr. H. O. Marcy dissenting, Dr. Hillis said that alcohol was under all circumstances the best tonic that we had, and that for it we should sacrifice willingly most of the drugs of the pharmacopoeia.

Phenyldihydrazin as a Test for Sugar in the Urine.—Dr. Coriat (Boston Medical and Surgical Journal, November 23rd) states that phenyldihydrazin forms a compound with different sugars, crystals, which in every case have a definite morphology, so that each sugar can be recognized by those crystals alone. Other substances, such as urea, uric acid, hippuric acid, creatinin, etc., which interfere with the ordinary clinical tests for sugar, do not affect this test.

To apply the phenyldihydrazin test to the urine, take twenty-five cubic centimetres of urine in a small beaker, and add one gramine of phenyldihydrazin and two grammes of sodium acetate. Heat over the water bath for from thirty minutes to an hour, and then cool by plunging the beaker in cold water. A yellow crystalline deposit is thrown down, which on examination by the microscope is found to consist of the yellow crystals of phenylglycosazine if this sugar is present.

An excess of phenyldihydrazin must be present in order that the crystals may be formed. The experiments set forth in his paper seem to the author to justify the following conclusions: 1. Phenyldihydrazin forms with the reducing sugars crystalline chemical compounds, each having an individual and definite morphology. 2. Albumin need not be removed. 3. It is possible to recognize any of the sugars by their crystalline forms alone, without recourse to their melting points. 4. Substances that interfere with Felhing's or Nylander's reagents do not interfere with this test, or form anything that would in any way be misleading. 5. The test is an extremely delicate one, and of undoubted accuracy.

Enteroptosis, or Glénard's Disease.—W. F. Hamilton (Montreal Medical Journal, September; Medicine, November) says that notwithstanding the conflicting views concerning the classification of cases under this head, it may be accepted as safe teaching, at least for the present, that enteroptosis may exist without subjective symptoms. The enteroptosis of Glénard is associated with the most pronounced subjective signs, chiefly of a neurasthenic type. In those cases where a pendulous abdomen is present, the nervous features are less pronounced than in thin subjects with flattened abdomen. Typical enteroptosis may result from inflammatory processes in the abdomen. Any of the abdominal organs may be displaced in this disease. Most frequently, however, the colon and small intestines, the stomach, the right kidney, and the liver are found in altered relations. The condition is due to an atony of the nervous system with a corresponding relaxation of the muscular structures of the body. Its predisposing causes are heredity, chronic disease, unhealthful methods of living, and the wearing of corsets. The disease is to be looked upon as a constitutional ailment.

The diagnosis of enteroptosis is comparatively easy. The epigastrum is hollow; the two lower quadrants of the abdomen, even with the patient in a reclining position, are often quite prominent. It is most important to determine the lesser curvature of the stomach and
its relation to the greater curvature. Where the lesser curvature can be demonstrated, some degree of displacement exists; the amount of displacement is to be measured by the relation of the lesser curvature to the umbilicus. Palpation usually reveals movable kidney, and the liver when displaced is usually more prominent in the epigastrium and may be easily rotated on its long axis. In the diagnosis of this affection Général laid special stress on a test which was applied by the examiner standing behind the patient, also in the erect position, and laying both hands flatly over the lower zone of the abdomen. Then firm but gentle pressure is made upward. In the great majority of cases this affords considerable relief to the distressing pain which is felt in the epigastrium and which is one of the patient’s chief complaints.

Dislocations and Fractures of the Astragalus.—Mr. Henry Gray Croly (Dublin Journal of Medical Science, October) says that on reviewing the cases which he has described as occurring in his own practice, of fractures and dislocations of the astragalus, and the cases which he has referred to recorded by surgical writers, he has come to the following conclusions, that: 1. The term “sub-astragaloid” is confusing and misleading. 2. In dislocation of the astragalus the bone is either partially or completely separated from its surrounding articulations, and if a wound exists, and any portion of the bone protrudes, it is compound. The direction in which the bone is displaced is specified by the terms forward, backward, outward, inward, etc. 3. In compound dislocation, with the head and neck protruding, the bone is so emulated that its vascular supply is cut off, and, though reduction might be effected, necrosis is certain to follow, necessitating the excision of the bone later on, and meantime risking the patient’s life by causing suppuration and septic trouble. 4. In compound fractures the sooner the bone is excised the better, the joint being drained. 5. In all simple partial luxations reduction should be attempted, and most probably success will be the reward of such praiseworthy efforts on the part of the surgeon. Tenotomy of the tendo Achillis or tibial tendons may in some cases be considered necessary. In the complete simple or double luxation, where the astragalus has left its box, no efforts on the part of the surgeon will effect replacement of the bone, and if its particular surfaces have undergone a change of position the bone must ultimately necrose. The author advises immediate excision in these “Listerian” days as safer than allowing the bone to slough out, which always happens except in cases of luxation backward, when it may be allowed to remain.

Mr. Turner says, in his experience in the majority of cases of dislocation of the astragalus there is an accompanying fracture of the bone. The bone may be fractured in the operation of extracting. Larrey and Boyer are in favor of extracting at once. It may be summarily stated in simple, direct, and complete luxation Turner advocates allowing the bone to remain in its new situation without any operation until it manifests a tendency to ulcerate the skin. To relieve tension an incision may be made over the dislocated bone, but its removal should be postponed. In complete compound luxation he advocates immediate removal. Boyer says after the astragalus is extracted the tibia is approximated to the os calcis. The movements of the foot are abolished, and the member loses a part of its length equal to the height of the astragalus. Boyer dissected a limb of a patient of Desault’s, and found the tibia almost ankylosed with the calcaneum, but it does not follow that ankylosis should result. Mr. Smith (Leeds) says his patient in each case had an excellent hinge joint of the tibia on the os calcis. In incomplete luxations of the astragalus the hooklike process of the astragalus may get fixed in the groove of the os calcis. In dislocations backward, allowing the bone to remain in its new situation has been most satisfactory.

Acetanilide in Post-partum Pyrexia.—Major Peck, R. A. M. C. (British Medical Journal, October 14th), speaking to a paper presented to the British Medical Association on Fever following Delivery, said that coming from India, he had seen a good deal of pyrexia and had used a number of antipyretics. In certain cases, no doubt, the usual antipyretics were very badly borne, and might doubtless cause a dangerous degree of exhaustion and depression. In other cases, however, they diminished the danger and discomfort of high temperature, and placed the patient in a better condition to weather the storm. He remembered a case of his own that occurred in India a few years ago. The treatment was practically confined to the administration of acetanilide whenever the temperature reached 104° F. The case was a bad one, and the patient’s condition remained critical for ten days. She experienced extreme discomfort and exhaustion whenever her temperature rose, and the administration of acetanilide reduced the temperature and enabled her to take nourishment and obtain rest until the poison had all been eliminated.

The Central Nervous System in Acute Malarial Infection.—At a recent meeting of the New York Neurological Society Dr. James Ewing (Journal of Nervous and Mental Diseases, November), after describing three cases, said that when the brain cortex was markedly brownish it indicated usually the presence of a large number of parasites, but this was not an invariable rule. The majority of cases of comatose malaria did not exhibit the massing of the parasites in the brain. Of eight cases in which he had examined the brain after death, in none was there a distinct brownish discoloration of the brain. Hæmorrhages had been found in some cases, as had also a moderate degree of edema. Usually the parasites were uniformly distributed in the brain and cord, but a case had been reported in which they were localized in the medulla. The number of these parasites was often enormous, and complete occlusion of the vessels was not at all uncommon. While most of the fixed pigment was found in the endothelium, the parasites were rarely seen in the endothelial cells. It was probably safe to refer the cerebral symptoms observed in these severe cases of malarial infection to the general condition of the obstructed circulation. The ganglion cells, in cases of comatose malaria, had been studied, and the changes found to consist chiefly in the various degrees of chromatolysis. The dendrites were usually involved before the cell body. The ganglion cells appeared to suffer less than in the average case of typhoid fever. The mere presence of the parasites in the tissues seemed to exert no bad influence, except in a mechanical way. In one of the cases reported in the paper the deepening of the coma could be apparently connected with the progressive filling of the capillaries with the parasites and the formation of thrombi. In the other two cases the parasites were few and the pigment scanty. In both of these cases the
malarial infection was exceedingly severe. These cases showed that the coma of malaria was not always referable to the presence of the cerebral parasites. Of the writer's sixty-four cases of malarial coma reported there were five simple tertian infections. In the astivo-
autumnal cases, with crescents only in the blood, there were thirty-four instances from the Montauk camp. Coma appeared to be rather frequent in cases showing only crescents in the blood. Crescents did not exhibit such a tendency to unequal distribution as did the tertile forms. From the condition of the viscera found in the second and third cases reported—and this variety occurred especially in cachectic individuals in whom the disease had existed for some weeks—it seemed probable that the coma was the result of the general and profound malarial infection. The writer did not believe that much importance should be attached at the present time to the condition of the ganglion cells in malaria. When the coma resulted from the massing of the young parasites in the brain, it was generally gradual in onset, and the prognosis was very unfavorable. In some cases the coma developed suddenly and was more amenable to appropriate treatment. The general clinic character of these cases indicated that an embolic process was concerned in their causation. Of eleven cases of the first class, reported by the writer, ten proved fatal.

To summarize: The three anatomical conditions were:
1. The mechanical obstruction of the cerebral capillaries by large numbers of young parasites. 2. An embolic process causing an occlusion of some vessels (usually temporary) by parasites or pigmented leucocytes. 3. A general toxemia, such as might occur in other infectious diseases, the blood showing few, if any, auricular rings.

Artificial Serum-therapy in Toxic Dermatoses.—Dr. I. Callari (Riforma medica, August 22d) terminates a series of articles on this subject with the following conclusions:
1. The antitoxic and toxic theory of the genesis of certain dermatoses (psoriasis, eczema, prurigo and pruritus, lichen planus and lichen scrofulosorum, ichthyosis, pemphigus, etc.) is the most rational. 2. The method of lavage of the organism with artificial serum in the sudoriferous dermatoses is a method sufficiently attested to remove it from the category of merely Utopian ideas. 3. Its efficacy in general can not be doubted, seeing that lavage (a) raises the blood pressure; (b) by flooding the blood dilutes the circulating toxins; (c) excites the eliminating functions; (d) modifies probably all the altered tissue elements; (e) by exciting the functional activity of hemato poetic organs probably augments their phagocytic powers; (f) by augmenting the number of red blood-corpuscles and the hemoglobin mass influences the general nutrition, determining an increase in the body weight. 4. The method of lavage is still susceptible of modification by varying the nature and quantity of the principal chemical elements entering into the constitution of the fluid—looking to data to be furnished when urology, hematology, histobi ochemistry, etc., shall have thrown some light on the complex problem of self-intoxication.

The Therapeutic Uses of Epsom Salts.—Dr. J. C. Culbertson (Journal of the American Medical Association, November 18th) says that notwithstanding all that has been written and stated so favorably as to the use of this potent remedy, he is inclined to believe that it is not yet fully appreciated for its many virtues. It may seem strange and even presumptuous to say this, in view of all that has been said, and in the face of the fact that sulphate of magnesium has become a universal domestic remedy. However, as used by the people, it is only as a simple, safe purgative that it finds place in everyday family use. In this rank it holds precedence always. As a purgative, its most common administration is in the morning, and in a dose of from half an ounce to an ounce. This may be greatly improved upon by giving from half a drachm to a drachm, administered in a pint of water. The mechanical effects of the water are beneficial and aid in establishing increased peristaltic action of the bowels. The remedy, when given in this manner, is peculiarly cooling and refrigerant. The same dose given at bedtime rarely acts even as a laxative, but becomes a most excellent diuretic, and also stimulates the skin so as to literally rid the body of accumulations of detritus, wherever they may be located. This is a property possessed in a high degree by sulphate of magnesium. In fact, it may be placed at the very head of the column of diuretics, as it is safe, and in action.

For a cure of dysuria it comes nearer to being a specific than any other remedy at our command. In giving it in this disease from a drachm to an ounce may be used. If large doses are given the discharges are apt to be stopped too abruptly; a drachm is better than an ounce and may be repeated every hour or two.

For the relief and cure of sick headache it should be given in doses of from half a drachm to a drachm every morning, dissolved in a goblet of water. Equally good results or even better may be obtained by administering it at bedtime. The goblet or pint of water should be insisted on with every dose. The temperature of the water may be that which is most agreeable to the patient, although Dr. Culbertson thinks warm water, say 100° F., more potent than that at a lower temperature.

In cases of hemorrhoids and all congested conditions of the rectum and other pelvic organs, sulphate of magnesium is almost specific in a large number of instances; where the patient is troubled with flatulence, the addition of peppermint to the salt solution is very effective in affording relief.

In gynecological cases, and particularly in peritonitis, sulphate of magnesium is again found at the top of the column of useful remedies. As a chologogue it is also in the front rank.

A Case of Congenital Impotence.—Belkowsky (Allgemeine Zeitschrift für Psychiatrie; Indian Medical Record, October 25th) describes the case of a man who, although married for four years, had never been able to perform the sexual act. In spite of the fact that his genitals were normal in development and his general bodily condition was excellent, he was totally devoid of sexual sensations, had never in his life had erections, and only quite lately had he had some nocturnal emissions, accompanied, however, by only imperfect erections. He was totally indifferent to the female sex, but no trace of sexual perversion could be observed.

The Influence of Food on the Age at which Babies begin to Walk.—Chamnier (Klinisch-therapeutische Wochenschrift; Indian Medical Record, October 25th) has investigated 1,220 cases. At the age of ten months only 5.6 per cent. of bottle-fed babies could walk, whereas 12.7 per cent. of breast-fed babies could. At
eleven months 12.3 per cent. of bottle-fed but 21 per cent. of breast-fed babies walked. At twelve months 22 per cent. of the bottle-fed and 40 per cent. of the breast-fed babies walked. At the age of two years the figures are 91.7 per cent. of hand-fed and 97.8 per cent. of breast-fed babies.

"An Undoubted Case of Superfecation." — The
Medical Review of Reviews for October 25th quotes, under the foregoing heading, the following case:

Herz (Wiener medizinische Presse, 1899, No. 36) describes the case of a woman, aged twenty-two years, married for the past year. Menstruated several times after marriage, but amount scanty. Menses ceased at fifth month after marriage.

The time of the first menstruation after marriage was in mid-December, 1897; on September 21, 1898, the patient bore a healthy, fully developed child. In delivering the placenta the midwife's hand encountered an object within the uterus which she believed to be a second fetus. Nothing further was expelled, however, and the patient made the usual recovery. Upon getting up, the presence of a uterine tumor was readily made out.

Six weeks after the birth of the first child the mother again felt life; in fact, none of her people appeared to have any doubt that a second fetus was in the womb. The health, which had unmistakably failed at the time of the actual cessation of the menses, had become strikingly worse after the birth of the first child. Herz first saw the patient on January 18, 1899 (four months after the birth of the child), diagnosticated superfetation, and proceeded expectantly. The patient, however, became worse, and died on February 10th, in the ninth month of the pregnancy. Her people made no attempt to send for medical aid, on suppositions grounds, although emptying the uterus might have saved the mother. Death occurred from suffocation. The most severe symptoms during life had been edema of legs, dyspnoea, and refusal of nourishment.

A NEW PEDICLE NEEDLE.
By L. B. Owen, M.D.,
COLUMBIA, S. C.

In the operation for the removal of tumors, ovaries,
uterus, etc., when the parts are to be tied in sections
by the use of a needle threaded with a double ligature,
I have often felt the need of one different from any
other needle used for that purpose. The cut below
illustrates a needle recently made under my direction
by Messrs. George Tiemann & Co., which I think will
be of great assistance to all surgeons. In abdominal surgery the rate of mortality is greatly influenced (as all surgeons know) by the two following factors:

1. Time consumed in the operation, as the longer the operation the more liable the patient to shock, with the stomach more irritable, the blood more deoxidized, the greater depressing effects of the anesthesia, and the wound longer exposed.

2. The way in which the surgeon guards against hæmorrhage.

By the use of this needle several minutes can be saved, and the vessels can be secured with more certainty.

The difference between this needle and those in general use is that in this one the ligature is doubly crossed before the pedicle is transfixed, and in the other afterward. When this needle is threaded properly, the pedicle can be transfixed, the suture clipped near the eye, and each section ligated in a few seconds; while with the other the ligatures are crossed after they are clipped, and one must pull and saw at them for several minutes to see if they are crossed, and it is never certain that they are, and if they are not they are almost sure to slip, and the patient to die from hæmorrhage. The needle is threaded in the same manner as any other; then one end of the ligature is drawn into the pointed excavation in the end of the handle, the other end is carried under and over the suture on the opposite side, and brought back to the original side and drawn taut into the other wedge-shaped notch. The notch near the shoulder of the needle is designed as a receptacle to keep the sutures when they are locked, so that they may be parallel along the shaft of the needle.

**Miscellany.**

The Evolution of "Ketchup."—We quote the following from the Cleveland Journal of Medicine for November:

"One of the trials of our younger days was to spell the name of the sauce that was and still is pronounced "ketchup." Such as had mastered "e-a-t-s-u-p" were on the top shelf of culture. From catsup we filtered down to katsup, then to catchup, and finally to ketchup. A man over in New Jersey made a million dollars at bottling tomatoes, and married his daughter to a real prince. Now comes a man up in the interior of the Empire State of New York who offers "grape catchup" as the finest modern relish. It is made from "selected Catawba grapes," and beats the old-fashioned home-made tomato catsup to death.'

"The real fact in regard to the good old word ketchup is quite the reverse of the idea given above. It is one of those instances of overrefinement introduced by people who are a little too sensitive for plain English. As a matter of fact, the East Indian word kitlap was changed to ketchup. It was evidently revolting to people of culture to say ketch instead of catch, and the word was changed to catchup. It was then obvious that there was nothing to be caught about it, and that it must be derived from catsup, the association of ideas possibly coming from the resemblance in color to a tortoise-shell cat. Thus was the 'kit' evolved into a 'cat' along purely linguistic lines."

A Prototype of Christian Science.—Dr. Buchanan (St. Louis Courier of Medicine, October), in an interesting article on the Medical Customs of the Snohomish Indians, says:

"One peculiar belief, idea, or custom was the occasional treatment of a disease by personification and addressing it as though it was an actual living and sentient being. Nevertheless, this idea does not seem so irrational when we consider that many diseases were supposed to be due to the presence or influence of malign spirits. Of course, it would be little else than natural then to address the spirit or spirits present or causing the disease. I can remember once coming upon an old Indian in the woods. I was unseen and unheard. The poor old fellow not only had a severe attack of acute bronchitis, but had also been partially deaf for years. Between the exacerbations of coughing I heard him deliver a spirited address to his sickness as follows:

"'Oh, yes; you think you are going to kill me, but you are not! Why don't you kill me and be done with it, if you think you can do it? But you know you can't do it, that's why you do not do it. I know you and how you go about like this. Kill me and let me alone; I don't care at all' (with affected nonchalance)! 'You know you can not do it, and you know well enough that I am not afraid of you. So just kill me and be done with it, or else get out, one or the other, and right quick too!'

The Treatment of Corns.—Dr. George D. Monro (Cincinnati Lancet-Clinic), in a humorous letter dated November 11th, describes his visit, when suffering from corns, to a lady whose office bore the following sign:

Mrs. ———, Sherpodgist.
Corns Erased.
Bungyans Eraduated.
Finger and To Nales Manchurcd.

Dr. Monro says:

"I told the lady 'sherpodgist' I was a sufferer from corns, and I saw by her sign she erased them; that I would like to have mine erased. I took off my stocking. She took my foot in her lap and said: 'Yes, I see three gems in the little planx, and they require depilation.' I told her I did not look upon them as very precious gems (corns, I presume she meant); she was welcome to them if she would only remove them. She soaked the corns with peroxide of hydrogen and very dextrously removed them. She then applied boric acid and acetanilide mixed. She ordered me to keep cotton saturated with peroxide of hydrogen on them as much as I could. I have been very comfortable ever since. I asked her what a corn was, anyway. Her reply was: 'It is hot blood pressing against the cutrix.' I thought that was probably as good a definition as any.'

There is a great deal that is worthy of being taken to heart in Dr. Monro's comment:

"But, joking aside, I believe it is necessary for a physician to know something about the treatment of corns. In this age of fashionable shoes I think this
knowledge is required. Such treatment should not be allowed to drift into the hands of ignorant 'sherpod-gists.' No disease is more common than corns, and no disease is capable of producing more universal discomfort than corns. Ask a physician, however, what to do for corns, and he will recommend some placebo, and laugh about the wearing of tight shoes."

The Perniciousness of Hasty Generalization.—In commenting on Dr. Granville Bantock’s presidential address in the Section of Obstetrics and Gynaecology at the British Medical Association’s meeting, the Medical Review of Reviews for October has the following excellent remarks:

"In concluding his remarks, Dr. Bantock urged that medical writers should display more moderation and discretion in publishing alleged results of their investigations. It has latterly become the custom of a considerable majority of the vast army of writers who fill the pages of medical journals with immature and unproved deductions, to promulgate opinions and put forward conclusions based upon insufficient evidence. Thus, an operator decides that he will sew up his abdominal wounds in a particular manner, and he forthwith announces to the world that he has banished ventral hernia after abdominal section. He does not wait ten years, he does not even wait five years to see the results and ascertain the permanence or otherwise of his method. It is the indiscriminate and useless notices of such crude and unproved views that unhappily crowd the pages of most medical journals, and render reference and search for facts of definite practical value to the practitioner so difficult. The output of medical literature has become something enormous, and it is continually increasing. We heartily wish that medical writers would bear in mind the adage that ‘it is never safe to prophesy until one knows.’"

The Results of the Malaria Expedition to West Africa.—A correspondent to the Lancet, in its issue for October 14th, says that the experience of the expedition at Wilberforce has been exceedingly instructive and affords very strong evidence of the truth of the mosquito theory. Here but one genus of mosquito—anopheles—and but one species of that genus, lodged in the barrack of the regiment. Of over a hundred of these mosquitoes caught at various times during the period of seven weeks, twenty-six per cent. proved to be infected, some showing a few zygotes only, others many and containing numerous “germinal rods” or “zygoblasts” in their salivary glands. Simultaneously fresh cases of fever came daily to hospital, with tertian, quartan, or estivo-autumnal parasites in the blood of the patients. Further, mosquitoes allowed to feed on these patients proved on dissection two or three days later to be infected. Thus the complete history was easy to trace at Wilberforce and proved a good guide for work in other districts.

It may be mentioned that the bodies discovered by Ross and described by other authors and usually called “black spores” were never met with in any of the numerous mosquitoes found here. This tends to disprove their connection with malaria. It is a very common idea that mangrove swamps are good breeding grounds for mosquitoes and that they also play a prominent part in the production of malaria. During the search at Wilberforce for breeding places, in order to test every possibility, two swamps in the neighborhood were explored. One is an ordinary swampy tract forming a kind of terrace halfway down the hill on which Wilberforce stands, the other is a mangrove swamp at the base of the hill. In neither could any spot likely to form a breeding place for anopheles be found.

The whole experience of the expedition at Sierra Leone tends to prove very strikingly that mosquitoes of the genus anopheles can not travel far. The whole of Freetown has been explored for anopheles larvae puddles and their positions have been carefully indicated in a plan of the town. The distribution of these puddles is limited very strictly to the immediate vicinity of human habitations. In no place has a puddle containing larvae been found more than forty yards from a native hut.

Similarly, again, the distribution of the mosquitoes themselves. Tower Hill barracks, where the First West India regiment is stationed, is an admirable example. The hill is about two hundred and fifty feet high; a ring about half a mile wide immediately around the barracks is clear of native huts. Just beyond that distance puddles containing the larvae of anopheles have been discovered; on two sides, in the parts known as Soldier Town and Bambara Town, they were particularly numerous. But, although several times the whole of the barracks were searched, never was anopheles discovered. Mosquitoes of the genus culex are common—disused tubs, mortars, and other vessels in the immediate vicinity of the barracks were their breeding places. Cases of fever did occur among the men at these barracks, but, compared to the number at Wilberforce, they were very few, mostly relapse cases; while from “first-attack” cases it was easy to get the history that a week or fortnight previously the patients had slept in a native hut in the town.

The puddles containing anopheles larvae may be described as follows: 1. Rock puddles occurring in shallow hollows on the surface of the bare hard rock. These are often only from a few inches to one or two feet across and many of the smaller ones swarm with larvae. 2. Street-side puddles. These occur in the course of the rough, irregular ditches at the sides of the streets, which serve very badly as surface drains. In heavy rain they are flooded; afterward there is only a small stream expanding irregularly into puddles, generally containing a green alga and swelling with larvae. Later, all but the puddles, and in very dry weather even these, dry up. 3. Street puddles: pieces of water of various sizes up to several yards in length, very shallow, and simply collections in the lowest parts of badly made roads.

The members of the expedition suggest that these could be dealt with by the following means, and are of opinion that if the suggestions were carefully carried out in all parts of the town mosquitoes of the genus anopheles would be practically extinguished in the district. 1. Surface drainage. This would involve the construction of open drains with a good fall at the sides of many of the less important streets, as has already been done in the principal ones, and the construction of even road surfaces by leveling up with soil, etc. This method, to a poor colony, such as Sierra Leone, might prove an expensive one, hence two others have been suggested. 2. Treating the puddles regularly with such a reagent as kerosene to kill the larvae. 3. Sweeping out the puddles where possible.

It is evident that the two latter methods would have to be regularly employed twice or three times a week for a long period, perhaps twelve months, by intelligent
“sevengers” instructed how to identify the larvae of anophelines. Experiments have been made here with kerosene sprinkled over puddles, with the effect that the larvae were all killed after a few hours. The kerosene film must completely cover the surface and must be renewed, of course, after a shower of rain. These two methods are now being employed at Freetown, but only the method of surface drainage can be expected to yield satisfactory permanent results.

So far as can at present be made out, three species of anophelines have been met with—but of one, however, only a single specimen has been captured—a large, black-bodied mosquito with greyish wings. Of the other two it is impossible, without a more careful dipterological examination, to decide whether one is anything more than a smaller variety of the same species, but they appear alike in every point except size, one being almost twice the size of the other. They have in common a brown body; the costal margins of their wings are studded with black patches, while along the course of the veins of the wings are scattered small pigmented spots of brown color. The larvae of anophelines are smaller than those of culex, have no breathing tubes, and their tapering bodies are provided along their whole length with a number of fine bristles, by which they are prevented, by becoming entangled among the algal threads generally found in the puddles in which they live, from being washed away by heavy rains. The larva varies in color from a pale to a reddish brown, and often have during the first two or three days of their development a white streak just in front of the prothorax; later this disappears. Full grown they are about three eighths of an inch long.

The Extermination of Rats in Plague Districts.—

According to the Boston Medical and Surgical Journal for November 30th, it is alleged that in Algiers, where a case of plague had been reported, and where certain other cases of a suspicious character had occurred, the authorities sealed all the sewers hermetically and then burned chemical products, the fumes of which destroyed all the rats. This, says the Journal, is a step which might be followed with advantage by all municipalities threatened by plague.

The Lawrence Hospital, Columbus, Ohio.—We learn from the Ohio State Journal that a hospital for women has been incorporated to be established in Columbus, and that it is to be called the Lawrence Hospital, in honor of Dr. F. F. Lawrence, to whose efforts the institution will be largely indebted for its existence.

Automobiles for Physicians.—According to the Medical News for November 25th, an English medical man has traveled in his automobile five thousand miles in a year at a total working expense of one hundred and thirty dollars.

The Physiological Fitness and Use of Egg Membrane for Skin Grafting.—Dr. Louis Heitzmann makes the following abstract of and comments on the investigations into this subject of Professor Max Schüller in Berlin, as recorded by him in two papers—viz.: 1. Epithelium on the Inner Surface of the Shell Membrane of Chicken's Egg (Anatomischer Anzeiger, vol. xvi, 1899); 2. The Shell Membrane of the Chicken's Egg an Epithelial Membrane and its Application in Skin Grafting of Granulating Surfaces (Monatsschrift für Unfallheilkunde, No. 9, September, 1899).

Dr. Heitzmann says that Schüller had repeatedly observed rapid new formation of skin upon granulating surfaces after application of the inner surface of the shell membrane of a fresh chicken's egg. Believing that epithelial elements must be present in the shell membrane, he has examined it microscopically, and has succeeded in demonstrating broad epithelium, mostly with large nuclei upon its inner surface, or rather between it and the albumen. Though the epithelium can occasionally be seen in the fresh specimen upon examination with immersion lenses in water or glycerin, it becomes more distinct in colored specimens, the coloring matters used being alum hematoxylin and Bismarck brown, as well as other aniline colors and carmine. The coloring requires great care, lest the epithelium should be destroyed. In good specimens the large round or oval nuclei (or two smaller nuclei) have a darker color than the cell protoplasm, which appears pale, granular, lightly colored, the contours round, polyedral, or angular. At times, however, the nuclei are lighter than the protoplasm. The epithelial cells do not seem to be evenly distributed over the entire surface, but are usually found singly or in smaller groups, and only occasionally in larger masses. Pressure of the cover glass may be sufficient to destroy them, and too much care can not be given to decolorizing as well as to the general preparation of the specimens. In transverse sections the presence and relation of the epithelium to the shell membrane can be well studied. The membrane, carefully freed from the shell, is placed in alcohol, imbedded in celluloid, and hardened. The specimens are partly colored before removal from the shell, partly after being cut with the microtome, and the coloring matter used is either Bismarck brown or alum hematoxylin. The sections are examined either in glycerin, oil of lavender, bergamot oil, or in xylo! balsam. In such sections the epithelial cells are mostly spindle-shaped and disposed in a single layer. In the boiled egg they are found with greater difficulty. Seven illustrations are added to Schüller’s paper and plainly show the epithelium.

In the second work Schüller describes a number of cases in which he has been able to produce new formation of skin by application of the shell membrane. After pricking the shell of a fresh chicken’s egg and allowing the yolk and albumen to flow out, the shell membrane is removed from the shell in as large pieces as possible without touching or tearing the inner surface, and the latter is at once placed in contact with the granulating surface, previously cleaned and dried; it is kept in place by means of a bandage of sterilized gauze and absorbent cotton. Neither antiseptic lotions nor powders are to be employed, since they may easily injure the young epithelium, though they must have been used previously, to thoroughly prepare the wound. The bandage is usually changed after four days, and then the shell membrane can, as a rule, be easily lifted up. Below it a white or bluish-white epithelial layer can be noticed. Smaller granulating surfaces may be entirely covered with epithelia by this time. Such an epithelial covering is permanent, and there can be no doubt that the shell membrane itself produces the epithelium, and does not merely cause a rapid production of epithelium from the surrounding portions of the skin. A characteristic case is the following: A little girl of ten months was brought for treatment on account of an
extensive scalding of the left upper arm, the elbow, and the forearm, which had taken place two weeks previously. The skin was necrotic to a great degree. After treatment with sublimate bandages and later with nitrate-of-silver salve, two granulating surfaces remained, one on the upper arm, about seven centimetres long, the other somewhat smaller in the upper third of the forearm. Four days after application of the inner surface of the shell membrane, new epithelial formations, about the size of a cherry, were noticed beneath the shell membrane, and the subsequent new formation of skin took place very rapidly. The entire healing process was excellent, and there was no contraction from the scar. The author has been able to make similar observations continually, and in one case a new epithelial formation could be observed after twenty-four hours.

Report of the Committee on the Pathology of Yellow Fever.—According to the Boston Medical and Surgical Journal for November 30th, the commission, consisting of Dr. E. Wasdin and Dr. H. D. Godding, sent by the United States government to Havana to inquire into the etiology of yellow fever, has arrived at the following conclusions:

"1. The micro-organism discovered by Sanarelli, and by him named the Bacillus icteroides, is the cause of yellow fever. 2. Yellow fever is naturally infectious to certain animals; in some rodents local infection is very quickly followed by blood infection, and, while in dogs and rabbits there is no evidence of this subsequent invasion of the blood, monkeys react to the infection the same as man. 3. Infection takes place by way of the respiratory tract, the primary colonization in this tract giving rise to the early manifestations of the disease. 4. In many cases of the disease, probably the majority, a primary infection or colonization in the lungs is followed by a secondary infection, or a second colonization of this organism in the blood of the patient. This secondary infection may be complicated by the instantaneous passage of other organisms into the blood, or this complication may arise during the last hours of life. 5. There is no evidence to support the theory advanced by Professor Sanarelli that this disease is primarily a septicemia, inasmuch as cases do occur in which the Bacillus icteroides can not be found in the blood or organs in which it might be deposited therefrom. 6. There exists no causal relationship between the bacillus X of Sternberg and this highly infectious disease, and the bacillus X is frequently found in the intestinal contents of normal animals and of man, as well as in the bronchial secretion. 7. So far as the commission is aware, the Bacillus icteroides is never found in any body other than one infected with yellow fever, and whatever may be the cultural similarities between this and other micro-organisms, it is characterized by a specificity which is distinctive. 8. The Bacillus icteroides is very susceptible to the influences injurious to bacterial life, and that it is readily controlled by the processes of disinfection, chemical and mechanical, is assumed. 9. The Bacillus icteroides produces in vitro as well as in vivo a toxine of the most marked potency, and from our present knowledge there exists a reasonable possibility of the ultimate production of an antitoxin more potent than that of Professor Sanarelli. As there is such a wide divergence of opinion with reference to the Bacillus icteroides in its relation to yellow fever, the committee believes the organization of an able and full commission of bacteriologists, fully equipped and provided with ample means, should be effected, which shall be permanently located in one of the yellow-fever infected cities. Sufficient remuneration should be provided, so that the highest talent in bacteriology may be engaged."

Celtic Medicine, its History and Lessons.—This was one of the headings of an address delivered in the Mator Misericordiae Hospital, Dublin, on October 23d, by Thomas More Madden, to whom we are indebted for advance proof sheets of the address. Dr. Madden said:

"In this connection I may for a moment refer to the too generally forgotten fact that Irish medical men can lay claim not only to the traditions they inherit from their more immediate predecessors, but also to a history deserving of larger consideration than is now commonly given to it. For, as I have elsewhere shown, the practitioners of the healing art in this country are, in truth, the legitimate heirs of the oldest professional culture of which there are in existence the records in the living language of any European nation. Let me, therefore, remind you that in distant ages, when the lamp of medical knowledge was unkindled in most other countries, its light shone with comparative brilliancy in this remote Ultima Thule, as may be easily proved by incontrovertible historical evidence. Thus, for instance, there are still extant and accessible in the libraries of the Royal Irish Academy and Trinity College in this city, as well as in other similar collections elsewhere, a vast body of ancient Gaelic MS. documents in many of which the distinguished history and high character of early Irish medicine are well illustrated.

From these sources we find that from the oldest period of authentic history the classic literature of Greek and Roman medicine was cultivated, therapeutic, materia medica, and anatomy were studied, and surgery, gynaecology, and obstetrics were practised in Ireland, where the practitioners of the healing art were then held in high honor. Nay, more, we have clear evidence, which I have elsewhere sufficiently adduced, to show that the alleged marvels of modern hypnoses and the employment of anaesthetics, on which we plume ourselves as the most beneficent discovery of the present age, were, although in cruder forms, here anticipated by our remote predecessors.

Among the numerous collegiate centres of professional as well as of ecclesiastical learning with which thisinsula sanctorum et doctorum was studded between the sixth and sixteenth centuries, and the very ruins of many of which, such as Clonmacnois, Cashel, Meelick, Portumna, and Monasterboice, still attest the culture and art as well as the piety of their founders, one, at least, is of special interest to us as of a distinctly medical origin and character—viz.: Tuaim Dreachain, near the present town of Beltrurt. This college, as Dr. Healy, bishop of Clonfert, has shown, was established by a medical practitioner of no little eminence, Saint Brecin, whose chirurgical skill, more especially in cerebral surgery, is celebrated in our oldest annals.

All the various faculties of these Celtic Catholic universities, for such was the character of many of them, were for long ages crowded with students from every part of Europe, who in some of them were subjected to a course extending over a period far more protracted than even that of the modern medical student. From these institutions also were sent forth men such as Aeluín, the founder of the University of Pisa, Johannes Scotus Erigena, the first professor of philoso-
phy in Oxford, and countless others to diffuse the lights of learning and science as well as of faith to the ends of the earth.

Nor did that long intellectual preeminence cease, in medicine at least, until after the destruction of the Irish monastic universities during the reigns of Henry VIII and Elizabeth, and down to the early part of the seventeenth century we find the far-extending fame of Irish medicine referred to by authorities of such eminence as Van Helmont.

From the destruction of those Celtic universities may, moreover, be dated the origin of the disabilities in the matter of higher education that for three centuries have pressed and still press heavily on the majority of the Irish people, and on none more forcibly than on those of them belonging, as so many here do, to the medical profession.

The latter, during all these generations, have been thus unfairly handicapped in the race of existence by the impossibility of securing, in accordance with their consciences convictions, that full measure of academic training within the halls of a university which is so conducive to success in the higher walks of professional life or public employment, and which is accessible to their compères of every other persuasion.

We may, however, rest well assured that in this, as in all other matters, justice, although long delayed, must, like that truth on which it is founded, eventually prevail. And therefore can we confidently expect that this last vestige of the dark shadows cast o'er our land by the successful intolerance of a bygone age may forever be swept away in the near daydawn of the twentieth century, which we trust will usher in the final and equitable settlement of the Irish university question.

Whether in our day this long-cherished hope is realized or not, will, however, we are equally confident, in no wise affect your kindly relations and zealous cooperation in the mission of medicine with your brother practitioners of all other schools and denominations. Nor need an attempt at stimulating your esteem and respect for men among whose professional ancestors were included names such as those of Cusack, Carmichael, Graves, or Stokes, which at home and abroad are as imperishably engraved on the annals of our science as those of our Catholic compères, Corrigan, Lyons, or Hayden, or who, like the Anglican founder of Sir Patrick Dunn's Hospital, or Bartholomew Moss, to whom Ireland owes her great school of midwifery, the Rotunda, have left in our city enduring monuments of a medical benevolence as far above all sectarian considerations as that of the founders of the four Catholic hospitals which are so largely supported by Irish charity in Dublin.

The New York Academy of Medicine.—At the last stated meeting, on Thursday evening, the 7th inst., Dr. Frederick A. Packard, of Philadelphia, delivered the Wesley M. Carpenter lecture, entitled Researches on Infection by the Tonsils.

At the next meeting of the Section in Surgery, on Monday evening, the 11th inst., the following cases will be presented: Prostatectomy, by Dr. Alexander B. Johnson; prostatectomy in a patient seventy-one years old, by Dr. Forbes Hawkes; the result of removal of floating cartilage from the knee joint, by Dr. B. F. Curtis; hip-joint amputation, by Dr. William B. Coley; and abscess of the liver, by Dr. Ramon Guiteras. Dr. Willy Meyer will exhibit Nitze and Casper's operating cystoscope and Bottini's prostate cauterizer improved by Freudenberg. Dr. John F. Erdmann will present a foreign body in the knee joint formed by a piece chipped from the cartilage.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, the 12th inst., cases will be reported, patients will be presented, and specimens and new instruments will be exhibited.

At the next meeting of the Section in Pediatrics, on Thursday evening, the 14th inst., a discussion on the Mortality and Treatment of Acute Intussusception will be opened by Dr. Frederick Kammerer and continued by Dr. Robert Abbe, Dr. Frank Hartley, Dr. F. H. Wiggins, Dr. Willy Meyer, Dr. A. Jacobi, Dr. Francis Huber, and Dr. John Dornin. Cases will be presented and new instruments will be exhibited.

At the next meeting of the Section in Orthopaedic Surgery, on Friday evening, the 15th inst., Dr. Newton M. Shaffer will read a paper entitled The Convalescent Stage of Hip-Joint Disease, with Special Reference to the Question of the Abolition of Protection to the Articulation.

Delicacies for the Sick.—The New York Exchange for Women's Work calls attention to its domestic department, which will furnish all kinds of home-made delicacies for the sick at short notice. This exchange is a charitable institution designed to help refined women in reduced circumstances, and is supported by voluntary contributions. Not only are orders sent to it well filled, but physicians who patronize the exchange will be assisted one of our most worthy charities. The exchange is at No. 334 Madison Avenue, corner of Forty-third Street. The telephone number is 1225 Thirty-eighth Street.

St. Vincent's Hospital.—Dr. José M. Ferrer and Dr. Charles H. Lewis have been appointed visiting physicians to the hospital.

The Mariani Wine of Coca.—In a recent communication M. Mariani, of Paris—whose researches into the medicinal properties of coca leaves and the pharmaceutical processes most suitable for preserving those properties unimpaired extend back nearly fifty years—speaks feelingly of the imputations which have been cast upon coca itself on account of the occasional sad results of the use of the alkaloid cocaine, and no less pointedly of the reproach to which his preparation, vin Mariani à la coca du Pérou, has sometimes been subjected because of the unsatisfactory results obtained with one or another of the many wines of coca that have been placed on the market. M. Mariani lays stress on the care taken in his large establishment in the preparation of his product and on the wholesome character of the wine used. He insists anew on the necessity of blending in due proportions the leaves of several varieties of the coca plant in order to bring out their most desirable tonic and sustaining action, and says that a more vinous solution of cocaine, alone or in various artificial combinations, such as many of the so-called wines of coca unquestionably are, is in no wise capable of giving the results that physicians expect when they prescribe the vin Mariani as an indifferent. He points out that the market of such preparations is short-lived, and maintains that fact in itself fully proves his contention, which, moreover, is sustained by letters that he has received from more than eight thousand physicians.
Original Communications.

MICROCOCCUS INTERTRIGINIS ROSSBACH,
By MAX MEYER, M. D., Ph. D.

The etiology of certain diseases of the skin has been demonstrated to be bacterial, and to-day I can add the

Micrococcus intertriginis Rossbach as the producer of erythema intertrigo.

Only after long and exhaustive researches was I successful in isolating a micro-organism which proves beyond doubt to be the cause of the disease.

Aetiology.—Erythema intertrigo is generally found between the folds of the skin. Uncleanliness, irritable epidermis, or profuse perspiration will produce the disease. The surfaces become rough, hyperæmia occurs, reddening of the irritated area takes place, affording a suitable soil for the development of the germ, which, multiplying steadily, penetrates into the deeper layers and excretes an irritating, cheesy, ill-smelling, white material, infecting the surrounding tissue. Inflammation with all its symptoms sets in, the formation of pus goes on, and the final result is ulceration.

Biological Characteristics.—From a pronounced case of erythema intertrigo a small amount of the caseous
material was introduced by means of a sterilized platinum loop into the following media: Petri dish—nutrient gelatin, glucose-gelatin, agar; culture tube—nutrient gelatin, agar, serum; potato; milk. The growth on the different media was good but rather slow.

(a) On Petri Dishes.—The colonies were spherical in shape, with fine serrated margin, and light-yellow in color. The gelatin was liquefied, forming at first a shallow depression which became gradually funnel-shaped, leaving in its concavity the fluid gelatin mixed with the colonies. A very offensive odor like rotten cheese was perceptible, especially in the gelatin cultures.

(b) On the Culture Tubes.—A growth similar to that on the Petri dishes appeared. The gelatin stab cultures grew slowly, sending out fine threads which anastomosed with each other, and after an incubation of three days a shallow depression appeared and liquefaction took place. This depression molded itself into a funnel-shaped cone, sending out threads which penetrated the medium and, gradually advancing, threw out very delicate anastomosing fibers to radiate in all directions. No gas formation was apparent and the medium was not colored. On agar the cultures grew on the surface only; they were not more than a tenth of an inch in diameter and crept slowly forward, accumulating in heaps. The appearance of the colonies was slightly yellow and without any gloss. The growth on serum was
moderately quick; the colonies covered the medium like a film of a light-yellow color.

On potatoes a yellowish-brown spot appeared from which the colonies spread, becoming lighter colored as they advanced.

Milk was not coagulated or acidified.

Indol reaction could not be observed.

**Morphology.**—The germ, as seen under the micro-diameter. It has no flagella nor spores. It is aerobic. Examination of the hanging drop does not reveal any independent motion. Occasionally the cocci heap together; at other times they form very short, chainlike threads.

**Staining.**—Specimens stain with watery aniline dyes, especially well with methylene blue, gentian violet, and fuchsine. After Gram they decolorize, but not completely.

**Pathogenesis.**—On animals inoculated with the pure culture by scarification the disease appeared within forty-eight hours, and cultures made from these inoculations produced the same germ, which proved to be virulent to the tenth generation.

**Therapy.**—The cocci grow best at body temperature. They are destroyed at 70° C. and below 10° C. Of all the antiseptics which have been tried, formaldehyde in a half-per-cent. solution seems to be most effective in killing the germ.

**Conclusion.**—Owing to the above facts, I may state that the researches made by me demonstrate positively
A STUDY OF
SHORTENING OF THE TIBIA AND FEMUR
IN FIFTY CASES OF
TUBERCULOUS DISEASE OF THE HIP JOINT.

By RUSSELL A. HIBBS, M.D.,
SURGEON TO THE NEW YORK ORTHOPAEDIC HOSPITAL;
FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

In studying the question of the causes of shortening of the limb in connection with tuberculous disease at the hip, from the writings upon this subject, one receives the impression that the principal cause is considered to be the destruction of bone.

This is probably due to the fact that suppuration, a conspicuous evidence of the destruction of tissue, occurs so frequently, which, with the shortening of the tibia obscured by the usual method of measuring the limb from the anterior superior spine of the ilium to the internal malleolus, suggests that the femur is chiefly affected and that bone is destroyed. It does not follow necessarily, however, that suppuration is evidence of the destruction of bone, as in many cases in which it is impute the destruction of bone is slight, while in others that have no suppuration it is considerable. Of one hundred and six cases of hip-joint disease reported by the writer, the greatest amount of shortening was found, as a rule, in those of the non-suppurative variety (New York Medical Journal, November 5, 1898). The importance of recognizing the amount of shortening of the tibia is obvious, since it, in not being due to the destruction of tissue, would serve to indicate to what extent shortening was due to other causes.

For the purposes of this discussion it would seem to simplify the matter to consider the causes of shortening of two varieties: First, the direct, that due to the destruction of tissue; second, the indirect, that due to a trophoneurotic affection which causes diminution in thickness as well as length of the bones and the interference with the growth of the limb by the impairment of function. The first of these causes would be effective only while the inflammatory process was active, and the same would probably be true of the second, so far as the trophoneurotic disturbances were concerned; but in the matter of interference with growth from impairment of function, this would continue effective so long as growth was possible and in proportion to the extent of such impairment, which will be greater or less, depending upon many considerations which it is not my purpose to discuss here, though in most cases there will result some impairment of function, as you will have observed. The fact that impairment of function and interference with growth incident to it will continue until growth has been attained renders the consideration of this cause in cases that have not attained their growth of less value.

* Read by invitation before the American Orthopedic Association at its thirteenth annual meeting, New York, June 2, 1899.

The Death of Professor Birch-Hirschfeld, the well-known pathological anatomist of Leipsic, is announced as having taken place recently.
but the difficulties in reporting a large number of cases that have attained their growth is obvious. The displacement of the head of the femur would have an important bearing upon the amount of shortening, but not being pertinent to this discussion it will not be considered, and no case has been included in this report in which it could be detected.

The fifty cases studied were observed in the New York Orthopaedic Dispensary and Hospital, and are arranged in the accompanying table. Their treatment was by the traction method as applied by the long traction hip splint, and the greater part of the time as dispensary patients.

The measurement of the femur was taken from the anterior superior spine of the ilium to the line of articulation between the femur and the tibia on the inner side of the knee joint, and the tibia from this point to the internal malleolus. This I believe to be a more accurate method of measuring these bones than to use the tuber of the tibia as a fixed point, though this also was done in most instances. I am indebted to Dr. E. J. Parish, the assistant resident surgeon of the hospital, for assisting me in measuring most of these cases.

In thirty-three cases, or sixty-six per cent., there was shortening of both the tibia and femur. In one the disease had existed less than one year, and there was a quarter of an inch shortening of the tibia and three quarters of an inch shortening of the femur. In eleven cases the disease had existed from two to four years, and the average shortening of the tibia was .23 of an inch; of the femur, .43 of an inch. In two of the latter the shortening of the tibia was greater than that of the femur, in two it was equal, and in the remaining seven the shortening of the femur was greatest.

In four cases the disease had existed from four to six years and the average shortening of the tibia was .43 of an inch; of the femur, .47 of an inch; the shortening of the tibia being the greatest in one, the shortening equal in one, and the shortening of the femur greater in two. In eleven cases the disease had existed from
six to eight years and the average shortening of the tibia was .54 of an inch; that of the femur, .94 of an inch. In one the shortening of the tibia was greater than that of the femur, in two the shortening was equal, and in eight the shortening of the femur was greatest.

In one case the disease had existed eight years, and the shortening of the tibia was an inch, and that of the femur, an inch and a quarter.

In the five remaining cases of this group the disease had existed from ten to fourteen years, and the average shortening of the tibia was .57, and that of the femur, 1.9 inch. This group presents the conditions that would be expected in most cases—shortening of both bones. Note that the greatest amount of shortening of the femur is found in those cases in which the duration of treatment by traction is shortest in comparison with the duration of the disease. Instance Case 36—the duration of the disease was fourteen years, while the duration of treatment by traction was six years; also Cases 25 and 19 are similar. Of course, these are the most conspicuous, but this will be found comparatively true of most of the cases. It is reasonable that such should be the case, as when traction is applied the effect of traumatism, an important element in increasing the activity of the disease, is minimized to the greatest degree.

There were two cases in which there was shortening of neither bone (43 and 50); the disease had existed in the former three years, in the latter four years and a half. And in two cases there was shortening only of the femur (Cases 2 and 45); the disease having existed in the former three years and a half, in the latter only eight months.

It is difficult to explain the non-existence of shortening of the tibia in three of the last four cases mentioned. There might have been a congenital difference between the lengths of the tibia, the one of the diseased limb being the longer. In one instance the short duration (eight months) of the disease explains its absence.

In two cases, Nos. 10 and 13, there was shortening of the tibia only; in the former the disease had existed three years and a half and in the latter a year and a third.

In the remaining eleven cases there was shortening of the tibia and lengthening of the femur. In four cases of this group, Nos. 1, 7, 14, and 27, in which the disease had existed, respectively, three years and a half, three years and a half, two years and a half, and two years, the lengthening of the femur was equal to the shortening of the tibia, thus showing the limbs of equal length; while in the remaining seven cases the lengthening of the femur was greater than the shortening of the tibia, thus showing lengthening of the limb, the amount varying from an eighth to half an inch. The duration of the disease in six cases was from two to three years and a half, and in one case seven years. Thus it may be seen from the conditions found in a group of cases how a measurement of the limb as a whole would give an incorrect impression of the effect of the disease, and emphasizes the importance of measuring these bones separately. I have no doubt that many of the cases reported as having no shortening or even lengthening of the limb are such as these, and if measured in the same way would present a similar condition.

The cause of this undoubtedly is a congestion of the epiphysis of the femur which is due to the inflammatory action of the disease, when in proximity to it, increasing the activity of its growth.

A similar condition is often seen in the course of knee-joint disease where there is lengthening of either or both bones. An increased activity of the growth of the femur at this point may be sufficient to prevent shortening of the limb, or even produce lengthening for a time in the course of the disease, as was true in these cases; in one the disease had existed seven years (Case 8); but it is doubtful if this activity of growth will be sufficient to counterbalance the more constant causes of shortening and prevent their appearing ultimately some shortening of the limb. Measurements taken of the case just mentioned (No. 8) eighteen months previous showed three quarters of an inch lengthening of the limb, while now there is only an eighth of an inch lengthening. This patient will unquestionably have a certain amount of shortening when he has attained his growth.

The important relation that exists between function and nutrition, and the well-known fact that shortening increases somewhat after the disease has become inactive, suggest the probability that this increase will continue as long as growth is possible. As the less active growth of the diseased limb is due to impaired function, a condition found as a result of this disease in most instances and one which is, as a rule, permanent, the increase of shortening will be proportionate to such impairment and to the years of growth to be attained.

I do not take the position that patients with tuberculous disease at the hip have not recovered with limbs of equal length after growth has been attained; but I think they are exceedingly rare, and are only such as have recovered from the disease very early in childhood, the treatment having been of short duration, with the normal function of the joint restored.

While shortening of both the tibia and femur is present in the large percentage of these cases, it would seem desirable, in order to arrive at some general conclusion as to the proportionate responsibility of these bones for the shortening of the limb, which would represent as truly the ultimate condition as possible, to consider only those cases in which the disease had existed longest, which are as well those nearest the end of the period of growth. There are thirteen such.
cases, the disease having existed from seven to fourteen years, their ages varying from ten to twenty-five years. The average shortening of the tibia was .70 of an inch, while that of the femur was 1.47 inch, thus showing the shortening of the femur about twice as great as that of the tibia. Whether this proportion will exist at a future period in the history of these cases it is impossible to say, though it is probable it will, in view of their age, the duration of the disease, and the inactivity of the disease in most instances. I would emphasize the importance of this fact, however, namely, that the knowledge of this proportion, whatever it may be in any case, furnishes a means by which a fairly correct estimate may be placed upon the causes of shortening as to their comparative responsibility for it. It is obvious that the destruction of tissue can play no part in the cause of shortening of the tibia, though one half of the entire shortening of the limb is represented by that bone in these cases. If the indirect causes of shortening, the trophoneurotic affection caused by this disease, and the interference with growth by impairment of function, produce this effect upon the tibia, it is fair to assume that the femur will also be affected in this way to as great a degree, which fact suggests that destruction of tissue, the direct cause of shortening, is of less importance than the indirect causes, probably producing not more than one third of the total amount.

In all of these cases in which the disease had existed any considerable length of time the foot of the affected limb was smaller. That the diminution in the thickness of the tibia might be appreciated, radiographs of the tibia were made in many instances, those of two cases only accompanying this report, being sufficient to illustrate what was true of all that were examined in this way. These cases are Nos. 5 and 38, the disease having existed seven years in both instances. It is probable that radiographs will show diminution in the thickness of this bone as well as that of the femur earlier than shortening can be detected by measurements.

CONFINED SUPPURATION OF THE FRONTAL SINUS,
WITH SPONTANEOUS RUPTURE,
INCLUDING THE REPORT OF A CASE.+

BY D. BRADEN KYLE, M. D.,
PHILADELPHIA.

While there is nothing unusual in the fact that a suppurrative process occurred in the frontal sinus, yet the case which I wish to report to you is of such interest, not only in the course pursued by the disease, but in the symptoms produced, the age of the patient, the history of slight clinical phenomena, together with the external necrosis and spontaneous opening, as to render it worthy of report. The history is as follows:

Mrs. A. L. C., aged sixty years. In January, 1898, after being indisposed for a few days, she experienced a sensation of fullness on the left side of the nose, opposite the inner angle of the orbit. There was no pain, only a sense of uncomfortable fullness. There was a considerable discharge from the nose of a thin, watery secretion; the character of the secretion varied slightly in the morning, when it was thick and tenacious. There was a great deal of swelling over the face, especially between the eyes, which gave a peculiar facial expression, as though the eyes were wide set. There

+ Read before the American Laryngological Association at its twenty-first annual congress.
was not much tenderness on pressure over the swollen area. There was, however, some soreness at the inner angle of the eye over the region of the ethmoid cells. During the month of February the patient had quite a severe attack of epidemic influenza or la grippe. She was confined to her house about a month. During this attack there was practically no change in the condition of the forehead. The swelling remained about the same, and there was possibly a slight increase in the clinical phenomena. However, after the patient was able to be up, which was about the 1st of April, the swelling became more marked, especially under the eyes and on the left side in the region of the nason, about an inch and a half above the base of the nose. There was considerable discharge from the nostril, possibly more puslike, although nothing more than would be from an ordinary continued rhinitis. There was more soreness at this time, although not painful; the patient complained of malaise and a peculiar sick feeling; there was marked general debility, and the patient seemed to be failing very fast in general health. Prior to this attack she had been in the best of health—had never up to that time suffered from a headache. During the month of May the patient developed marked swelling in the limbs—in fact, all the symptoms were aggravated; there were sore spots here and there over the limbs, with some petechiae and slight inflammation. There was constant shifting of these spots. There were pronounced aching about the joints and symptoms of a decided rheumatic condition or gouty diathesis. There was very little change in the swelling of the face; if any difference, it was more marked. At no time was there any acute pain, the prominent symptom being the edematous condition. The history as given was furnished by Dr. Brouwer and Dr. Schurman. The patient had lost over thirty pounds in flesh, and was quite weak and debilitated. The last of June she consulted me, when I found the following conditions present:

The tissue on the forehead was so swollen that it hung down over both supraorbital ridges, with marked swelling under both eyes, especially the left, giving the patient's face a most peculiar appearance. In the median line, about an inch above the line of the supraorbital ridge, was a marked projection, almost tumor-like, with distinct redness, and somewhat pitted in the centre, with a small spot on which there was some dried secretion. On examination of the nose I found practically no discharge on the right side, only a slightly catarrhal inflammation; the left side was markedly edematous; the mucous membrane was covered with a thin, glairy discharge, with tendency to accumulation. The upper part of the nostril was so edematous and swollen as to completely occlude the cavity. This tissue was depilated by the local use of an eight-per cent. solution of cocaine, and after retraction of the tissue I could elicit no discharge from the openings of any of the accessory cavities. After the use of the cocaine there was perfect breathing through the nostril. There was practically no pathological alteration within the nasal structure, the septum being almost straight, and there was no enlargement of the turbinal bodies or lining membrane. Transillumination was resorted to, from a diagnostic standpoint, and the antra showed a perfectly clear outline. I was unable to make any satisfactory illumination of the frontal sinus or of the upper portion of the nose; however, I believed I had to deal with a confined suppuration in the left frontal sinus, or possibly involving both sinuses.

In passing a probe over the skin at the point of bulging with pitting, on removal of the slight crust formation I found that the necrotic tissue had given way and the abscess was already opened externally. On pressure, and by the patient leaning forward, there was a discharge of foul-smelling thick pus, and by slight digital examination I found that there was a necrotic area, almost circular, about three fourths of an inch in diameter. I then passed a probe into the opening, and, allowing it to follow the line of least resistance, it passed down without any force whatever, until it lodged against a soft material. By tapping it gently I felt that it was necrotic bone. With a little pressure the probe was passed through into the nasal cavity. At the same time light was reflected into the nostril, and the point of the probe could be seen on the septum side of the middle turbinate, about the middle third. I then had free drainage. After the discharge of pus the sense of fullness at the inner angle of the orbit, which had continued from the first, entirely disappeared. The cavity was flushed out with warm boric-acid solution, followed by hydrogen peroxide, cinnamon water, and aqueous extract of hamamelis, equal parts. Within forty-eight hours the swelling had entirely disappeared from the face. The time from the spontaneous opening of the abscess until the complete closure of the wound was about two months. Occasionally the external opening would become occluded with dried secretion with slight return of the facial swelling; on reestablishment of drainage this quickly disappeared. The patient's general health was improved by internal medication. Urinary examination showed no structural lesion of the kidney, but some leakage of serum albumin, possibly from relaxed blood-vessels. The internal medication consisted of Basham's mixture in drachm doses, as well as a sixteenth of a grain of the double sulphide of arsenic with a thirtieth of a grain of the nitrate of strychnine.

From the anatomical relation and histological structure it would seem more likely that the necrotic process would have involved the inner plate of the frontal bone instead of the outer; as to why in this individual case the necrosis involved the outer plate I can not explain. The edges of the necrosed bone were quite smooth and the opening almost a circular one, three quarters of an inch in diameter. The only surgical interference was the passing of the probe from the base of the cavity down into the nostril. It is my own opinion, and from the history of the case, that this began as a suppurating
catarrhal inflammation, and that in the inflammatory process the opening into the nasal cavity was occluded, for in passing the probe from the sinus into the nose I met with no bony structure, but simply granular and necrotic material. I had very little difficulty in keeping this passage open. Occasionally it was occluded by the accumulated dried secretion. My reason for nonsurgical interference was this, that if in the process of a confined suppuration the inner plate of the frontal bone and the other structures involved had resisted invasion to such an extent as to allow necrosis of the outer plate of the frontal bone there was no danger now of systemic infection from that source, and that if this structure had offered resistance during the confined suppuration, it was still a good protecting agent, and I reasoned that if the surface was freed from infection the sinus formed would fill in with granulations, and that by surgical interference I might only open up the lymphatics and blood-vessels and make an open way for systemic infection. The termination of the case proved my theory to be a correct one, for after thorough cleansing with antiseptic solutions and getting rid of all infection the opening healed by granulation, the bony part forming through the proliferation of the osteoblasts new bony structure, which, of course, obliterated the frontal sinus and gave a firm, solid wall. Whether there was an irregularity in the formation of the frontal sinuses I can not state, but either the left frontal sinus was abnormally large, or else the sinuses communicated, as the abscess cavity extended well to the right of the median line. The treatment consisted in the thorough syringing, first with a warm alkaline solution, followed by hydrogen peroxide, cinnamon water, and aqueous extract of hamamelis, equal parts. Suction was then applied and all this material drawn off. This was followed by a saturated solution of boric acid. By cleansing thoroughly the nasal cavity the solution would pass from the sinus into the left nasal cavity, showing the direct communication with the nose. After the first twenty-four hours I had little difficulty in keeping the sinus open, thus permitting through-and-through drainage. There was then blown into the cavity by means of an insufflator equal parts of boric acid and aristol. In the beginning I packed for three or four days, removing the packing each day, with gauze saturated with aristol. The nasal condition cleared up as soon as I was able to get rid of the infection in the sinus. This infected material of course flowed down over the nasal mucous membrane, producing marked irritation. The nasal discharge entirely ceased with the closure of the sinus, and now the patient is free from any catarrhal secretion, the nasal mucous membrane presenting a very normal appearance. The bony structure has filled in to such an extent that it leaves a very little depression and there is a very slight scar, as shown in the photograph.

You are all familiar with the recent literature on the subject, and many able articles on empyema of the frontal sinus have been published, but by a careful search of the literature I was unable to find a case identical from all standpoints. Morell Mackenzie (1) quotes a case reported by Richties in 1737 in which there was spontaneous discharge of caseous matter through the external table of the frontal bone and through the middle of the upper eyelid, which resulted fatally, evidently confined suppuration of the frontal sinus. Armstrong (2), in 1886, reports two cases of confined suppuration, but in neither spontaneous rupture; also a case of necrosis of the orbit plate of the frontal bone, following acute abscess, in which there was necrosed bone, but the discharge came through the nostril. He also reports three other cases of confined suppuration, but in all operative interference was instituted. Lennox Browne (6) reports a fatal case of suppuration of the frontal sinus, in which, on postmortem examination, it was found that the abscess had penetrated inward, and pus was found between the dura mater and the inner table of the frontal bone. C. Ramage (7) also reports a case of necrosis of the outer layer of the frontal bone, in which, however, the abscess was reached by incision. In all these cases there was a continuous discharge of pus from one or both nasal cavities, and there was not spontaneous rupture. Lawson (10) reports a case in which there was no discharge from the frontal sinus into the nose, and the abscess formation followed an injury. In his case the sinus was tapped through the nostril. Wells (11) reports a similar case of confined suppuration. Hodges (12) and Bousquet (13) both report cases of confined suppuration. Bousquet's case resulted fatally, and the autopsy showed the right frontal sinus full of caseous material, discharging through two openings, one into the cavity of the orbit and the other into the anterior lobe of the brain. Nicolai in 1724, and Runge and Richter in 1776, give the first clearly defined history of abscess of the frontal sinus. While the literature of abscess of the frontal sinus is replete with reported cases, yet, as I said earlier in the paper, I find practically none identical with the case above reported.

INGALS: FIBROUS TUMOR OF THE NASOPHARYNX.

[ N. Y. Med. Jour.,

14. C. S. Bull. Abscess of Both Frontal Sinuses. Medical Record, vol. xxxviii, 1885, p. 120.

FIBROUS TUMOR OF THE NASOPHARYNX.

By E. Fletcher Ingals, M.D.,

I desire to make a supplementary report of a case which, if I remember correctly, was presented to this association some years ago:

A man, now twenty-eight years of age, came to me when a boy of thirteen years with a fibrous tumor in the nasopharynx. I removed the tumor as thoroughly as possible, but some part of it which was attached to the vertical plate of the palate bone could not be eradicated. Finally, it began to crowd out beneath the zygomatic arch. The late Professor Gunn made an incision in the cheek from the angle of the mouth to the ear and attempted to remove it, but the hemorrhage was so profuse that he was obliged to check it as best he could without removing much of the growth. Not long afterward the boy became somewhat wild and was running about the city with no friends to care for him, so, fearing he would get into bad company, I sent word to his father to take him home. When he went home some of the growth was still present. This was fifteen years ago, and the patient now tells me that the growth continued to increase after he reached home for about a year, by which time the right nares was completely closed, the right malar bone had become very prominent, and he had lost the sight in the right eye. For many months the tumor continued without any considerable change and he had no treatment. In the course of a couple of years he again began to breathe a little through the nose. Afterward he steadily improved, until at the end of a couple of years the nasal cavity appeared perfectly free, and now he says the right cheek is growing smaller. His right eye appears nearly normal, but is blind.

A very interesting feature in this case is that the fibrous growth, which occupied the nose for four years, has disappeared. The right nasal cavity is now an inch in its lateral diameter, the septum is crowded away over to the left side, and the turbinate bodies have been destroyed by the pressure. There is a large opening into the sphenoid cells into which the growth formerly extended. The case is especially interesting as showing not only the tendency to recurrence of fibrous growths, but also a disappearance of this tendency as a person advances in life toward twenty-two years of age, and a possible tendency to complete atrophy, as in this case, in early adult life.

THE POTENTIALITIES OF THE PHYSICIAN.

By KENNETH W. MILLICAN, B.A., M.R.C.S.

(Concluded from page 851.)

3. We now come to our third division, the potentialities of the physician toward the community. And here the field is limitless, coterminous only with the whole social horizon. To quote Beverley Robinson again:

"We want our cities and towns to be thoroughly cleansed, the sewerage to be carefully and properly attended to, our streets to be well lighted, our health-board regulations to be governed with all scientific safeguards, looking to the common good and alike for the poor as well as for the rich. It is for us to insist upon, every day and at all times, the evils of our tenement-house system and the moral turpitude and physical debasement which necessarily proceed therefrom."

How well and thoroughly these things can be effected, even under the most unpromising conditions, has been demonstrated by the doctor-soldier-governor of Santiago. Hear how Mr. H. H. Lewis epitomizes General Wood's four months' work in that city:

"He has in that time accomplished," says Mr. Lewis, "the rescue of the population from starvation to a fair satisfaction of all their daily necessities. The conver-
sion of one of the foulest cities on earth to one of the cleanest. The reduction of an average daily death-rate of two hundred down to ten. A considerable progress in a scheme of street and road improvement that will add immensely to the convenience and beauty of the city. A radical reform in the customhouse service, resulting in increased revenues. A reduction in the municipal expenses. The correction of numerous abuses in the management of jails and hospitals, and in the care of the inmates. The liberation of many prisoners held on trivial or no charges. The reformation of the courts and a strict maintenance of law and order. The freedom of the press. A restoration of business confidence, and a recovery of trade and industry from utter stagnation to healthy activity.”

Is not that a glorious record for one physician?

But, you may say, Dr. Leonard Wood was acting as potentialities as a general and the governor of a province General Wood with plenary authority. What have his to do with the potentialities of the physician? Just this: Wood combined in his own person by a rare accident both the originating power and the executive authority. To the doctor was due much of the scheme, to the general the power to accomplish it. Let the physician learn, then, as Dr. Putnam says in the lecture before referred to, to become the educator of the community, that he may look to it for aid in the execution of that which he has devised.

But, besides sanitation, there are disease prevention by inoculation to be further studied, and the education of the public as to the enormous power and influence of “suggestion.” For, as some one has well said, “our lives are but the resultant of the suggestions around us.”

This subject is such a wide one, and so intensely fascinating in its study, as well as of such vital importance, that I am almost afraid to touch upon it lest I should be carried far beyond the permissible limits of this address. This much I will say, however, that it is proved beyond any reasonable cavil that through the mind the circulatory system can be influenced to a considerable extent, not only as a whole but in confined local areas. As familiar examples of the unconscious type may be mentioned blushing and the quickening of the heart’s action under the influence of alarm. There the suggestion operates on the mind from within to produce palpable effects in the material sphere. As an instance of the power of suggestion from without, it is well known that if one person in a group begins to yawn, sooner or later nearly every one in the group will follow suit.

And as with the circulation, so with the body temperature, the vegetative functions of the body, the inhibition of reflex action, and the perception of pain—all these under the influence of suggestion can be modified and to some extent controlled. In the heat and excitement of battle, in the concentration of mind and will power evolved in the effort to escape from imminent peril, and in the condition known as “a brown study,” that consciousness of severe nerve irritation which we call “pain” is often entirely lost until the mind is free to take cognizance of it once more. It is as though one should send a telegraphic message along a wire to a receiver at the other end. The message is transmitted, but, if the operator at the other end is busily engaged in some other occupation than attending to his instrument, it goes unheeded. Now, that operator may be inattentive, either on his own account because he has something else which he has inadvertently or willfully permitted to engross his attention, or through the agency of a friend who may have induced him to leave his office to “come across the road and have a drink.” Yet, whatever the cause of his inattention, the message, though duly transmitted, is never received, and fails of its effect.

Suggestion may operate upon the mind and through it control the physical operations of the body, whether originating from within or initiated from without, and in either case voluntarily or unconsciously. On the extent to which it can be voluntarily developed for the relief of pain, I should like to read a brief extract from an address delivered before the New South Wales Branch of the British Medical Association by the Hon. J. M. Creed,* a member of the legislative Council of New South Wales, and a physician of repute. Dr. Creed produced two gentlemen, “both highly intelligent men, possessing more than average business knowledge and common sense,” in whom he had been able to induce by repeated suggestion a capacity to become instantly insensible to pain at will. Dr. Creed said:

“On making use, either in my presence or when I am absent, of the arranged signal, which in the one is placing the forefinger of the left hand on the lips, in the other inserting the tip of either thumb between them, they instantly set up this extraordinary condition.

“To the bystanding observer there is no apparent change; they converse, go on with their occupation, and do everything just as if nothing had taken place; but in spite of all this they have, on using the signal, ceased to be sensible to pain. Nothing hurts them, and they can submit to being pricked, pinched, or otherwise maltreated without the slightest feeling. This you can test yourselves, for my patients, though, as you perceive, quite conscious of everything going on, will have no discomfort as the result of your efforts to hurt them. Nor are they only insensible to pain arising from injury inflicted while they are in this condition, but if at any time they have any, whether arising from accident or consequent on the morbid condition of any part (for instance, in toothache or neuralgia), by making use of the signal it ceases instantly.

“As a case in point, Mr. H. could, and if you wish it will, tell you how, when a considerable quantity of molten and flaming ‘Chatterton’s compound,’ the

* Australasian Medical Gazette, January 20, 1899.
melting point of which is very much higher than that of sealing wax, fell upon his hand, the torture from which would, under ordinary conditions, have been both lasting and intense, and which had actually commenced, he by making use of the arranged signal never for one moment felt the slightest discomfort from it. I did not see him until a week after the accident, when he showed me a deep wound from which the eschar had separated. A more crucial test than this it would be difficult to conceive, and yet he assures me that from the moment he touched his lips with his left forefinger he suffered no further pain. Some time after this he came to consult me, having accidentally torn his hand to an extent which necessitated the insertion of several stitches after antiseptic cleansing. He made use of his signal, and I did all that was necessary without his having a disagreeable sensation. He held his hand in any position I required, and assisted me in what I was doing, chatting all the time, being as interested and as little inconvenienced as if the little operation was being done on some one else. How long this condition would continue if left unchanged (sic) it is difficult to say, for I give my subjects the power to restore sensibility by another signal. I do this because, without the safeguard of pain, they might seriously injure themselves, and yet be unconscious of the occurrence. I would, however, point out that, though the power to feel pain from a fresh cause is restored, that which has been removed in this way does not return."

That this is no claptrap is shown by the footnote appended to Dr. Creed's paper by the editor of the Australasian Medical Gazette, in which the address was published, which reads as follows: "The subjects when requested produced the condition described, which was thoroughly tested by the members present, who found that, though completely conscious and in possession of the fullest mental acuteness, they were quite insensible to pain."

The bearing of these facts upon fads of all kinds, such as Christian Science and faith-healing in its various manifestations, is obvious. It is not the good effects which, in accordance with a general and now fairly well understood law of nature, they can produce that are objected to, but the absence of that knowledge and training which are essential to define the limitations of its influence, and to prevent its doing more harm than good, whether by the wasting of valuable time when other measures are imperatively necessary and must be resorted to in the end, or in cases in which the dangers are objective, not subjective, as in the case of the infectious diseases.

Among other potentialities of the physician in relation to the community I can only briefly refer to the ultimate elimination of tuberculosis and other transmissible diseases and to the furtherance of the procreation of a healthy race—not, I would venture to suggest, by undue restrictive legislation as regards marriage or divorce, which in my judgment will only inevitably replace that which is open by that which is clandestine, but by the education of men and women in the science of the relation of the sexes in its threefold nature—mental, emotional, and physical; by the training of defective children, in which, as borne witness to by Dr. Putnam in the Shattuck lecture, remarkable results have been attained both in Europe and in this country, and notably in the Massachusetts School for the Feebleminded; and also by what must follow as a corollary from the practical application of all the preceding factors—viz., the diminution of insanity and crime.

These are all broad issues upon which the physician can fruitfully labor with a view to the ultimate benefit of the community at large. But in order to enable him to attain the influence over the public mind necessary to render his labors effective, he must strive to maintain the right of his calling to be once again undeniably classed among the "learned professions." No doubt there never was a time when, absolutely speaking, the average learning and intelligence of the members of the medical profession were greater than they are at present; but, relatively to the standard of general improvement in that respect, can we with truth assert a like average preeminence of the physician over his fellows to that which was conceded of old time? Surely, his must be no narrow technical training, but one of breadth and expansiveness; not a mere skeleton of dry science, but a living thing of intensely human character. Apart from his life's work there is a something calling to every man to pursue it, if he will only heed. We can not all be poets, novelists, painters, but there is always some sphere of creative work beckoning to each of us. Let us, then, seek out for ourselves, each in his separate path, what it is, and then pursue it. While giving us rest for our tired faculties, it will rouse to activity others that are sleeping while we work, and will prevent them from atrophying.

And, finally, in all these things about which we have been thinking, there are certain general principles pleading for adoption. They are breadth, preparedness, earnestness, sincerity, and wholesouledness.

_Broadth_ is well expressed by that quaint little society of the Philistines which is authoritatively described as “organized to further good-fellowship among men and women who believe in allowing the widest liberty to individuality in thought and expression.”

Of _preparedness_, what better example can we take than Dewey? Mr. Barrett (Harper's Weekly, September 30th) quotes him as having said:

"I never expected that such an opportunity as this would be mine, and I did not especially hope for it, as that would have meant hoping for war; but time and time again I went over in my mind what I would do and how I would act, if I were in command during a battle.”
What this preparedness enabled him to accomplish everybody knows.

But to no one more than to the medical practitioner is the duty of preparing constantly to meet the emergency whose time of coming none can foresee, if it ever come at all, one of paramount obligation.

Of earnestness,* that gifted writer, Ella Wheeler Wilcox, says:

"The hurry of the times affects us so
In this swift rushing hour, we crowd, and press
And thrust each other backward as we go,
And do not pause to lay sufficient stress
Up that good, strong, true word, 'earnestness.'
In our impetuous haste, could we but know
Its full, deep meaning, its vast import, oh!
Then might we grasp the secret of success.

"In the reeding age, when men were great,
The bone and sinew of their purpose lay
In this one word. God likes an earnest soul;
Too earnest to be eager. Soon or late
It leaves the spent horde breathless by the way
And stands serene, triumphant, at the goal."

Of sincerity, one of the most beautiful stories, whether it be fact or fiction, that I have read is this: The Pope one day received in audience a great friend of Rénan, the agnostic. "Did he die impenitent?" asked the Pope. "I regret to have to answer, Yes, your Holiness," replied the friend. "Yet I am glad," responded the Pope, "for it proves that he was sincere, and the good God will judge him by his sincerity."

And, finally, as to wholesouledness, what better can I say to you than the words of Kipling,† who, speaking of that time after "Earth's last picture is painted " when, having been called from refreshment to labor, the "Master of All Good Workmen shall set us to work anew," says:

"And only the Master shall praise us, and only the Master shall blame;
And no one shall work for money, and no one shall work for fame;
But each for the joy of the working, and each, in his separate star,
Shall draw the Thing as he sees It for the God of Things as They Are!"

Euphthalmine; a New Mydriatic.—_Lyon médical_ for November 26th attributes the following to Dr. Grand-clément: A few drops of a colliryum containing three grains and three quarters of euphthalmine to one hundred and fifty grains of distilled water dilate the pupil at the end of from ten to twelve minutes, while accommodation is only disturbed for about an hour subsequently.

RHINEDEMA.*

By H. HOLBROOK CURTIS, M.D.

In none of the works on the nose and throat do I find mention made of nasal edema or dropisy, though I have encountered several well-marked cases clinically, where an undoubted edema has existed for a very long time, and has given rise to such severe manifestations that it seems warrantable to dignify the affection by a name, as has been done where an edema exists in other parts of the body, as anasarca, ascites, hydrops coeli, pulmonary edema, hydrocele, hydrocelephalus, etc. As regards the etiology of nasal dropisy, we must admit that the causation is more obscure than that of cardiac or renal dropisy. Ranvier has shown that ligation of the vena cava of a dog does not usually produce any edema of the extremities, but if one sciatic nerve is divided the limb on that side becomes at once edematous, the explanation being that as long as the nerve is intact the lymphatics are able to absorb all the fluid which exudes from the capillaries, but when the nerve is divided the arteries dilate and pour out more fluid than the lymphatics are able to absorb, hence the edema. This edema is not due to paralysis of the limb, but to paralysis of the vessels, for when the vaso-motor fibres which supply the sciatic are cut edema takes place without paralysis; but if the motor strands of the sacral plexus are cut before they are joined by the sympathetic fibres, we find a paralysis without edema. We may analogously regard the edema occurring in the nose as a vasomotor phenomenon either due to a paresis brought about by overexcitation of the vasomotor nerves or to a direct injury to the nerves themselves, either by pressure or disease.

If we had only this causation of edema our task would be simple. We know edema to be caused locally where impeded venous return causes a dilatation of the arteries, and also where the arteries are dilated by other causes without venous obstruction. Winniarter has shown that vessels in an inflamed part are more permeable than in healthy tissue, as instance by the infiltrated welt in scratching an urticaria.

Again, local edemas are caused by anemia. We are all familiar with the general dropesies of the kidney and heart. In the kidney those diseases which have the most albuminuria are productive of most dropisy, usually first evidenced in the eyelids.

Cardiac dropisy from regurgitation generally appears first in the feet. Local edemas about certain inflamed joints and tissues, not dependent on cardiac or kidney lesions, are due to the dilatation of vessels in inflamed parts.†

The habitual imbibition of large quantities of water

‡ Quain's _Dictionary_. Lander Brunton.
is often productive of infiltration of the mucous membrane of the larynx and nose. A prominent judge of this city applied to me some years ago for recurring oedema of the arytenoids, which I was able to trace to this cause. He made a practice of drinking two quarts of water during the night and much more through the day. No cardiac or renal disease existed, and he recovered by abstaining from water except in small quantity.

We must differentiate between a hyperplasia and a dropsy, and I am convinced that many cases of so-called winter hay fever are cases of true rhinoedema. In this connection it might be well to review that ever-interesting subject, to discriminate between it and a dropsy of the nose.

Hay fever, for want of a better term, has probably resisted treatment more effectually than any of the nasal affections for which we are called upon to prescribe. The particular pollen which gives rise to the vasomotor phenomena in individual cases must be ascertained by careful study, and only by a removal of the pathological factor for a number of years can we hope for a cure by climatic influences. (I will say in this connection that I am still experimenting with the immunizing extracts of flowers I reported a year ago.)

Three types of cases are to be considered, the anterior, the posterior, and general erectile irritations, which induce the stoppage of the meatus. The anterior tumefaction occurs sometimes independent of the posterior, and is characterized by intermittent excitation of the erectile tissues of both the inferior and middle turbinates anteriorly, with ofttimes a thickening of the tissues of the tubercle of the septum.

The posterior condition may obtain independently of the anterior, affecting only the erectile tissues on the posterior turbinate, or, again, a general hyperplasia may be present.

The emanations of certain animals, such as the cat, the mouse, the horse, etc., as well as certain vegetable pollens, may produce this tumefied condition. The exciting cause originates in all these cases from without, acting on a constitutionally susceptible membrane. In rhinoedema we find on inspection a very similar condition, except that there is a general infiltration of the entire lining membrane of the nose; and this not dependent on any extraneous cause, such as pollen, but found at all seasons, and in patients of every station in life. The tissues are more spongy and pale, with a bluish tint; the entire nose is stopped; cocaine, ischaemin, or any known agent does not cause contraction, the vasomotor paresis persists, and a true oedema supervenes. In certain cases this lasts for months, the nostrils remaining impervious. The nervous system becomes greatly depressed; hysteria and melancholia sometimes follow. In one case I encountered the mucous membrane broke down in ulcerated areas, both on the septum and turbinates. In other cases the nose becomes filled with a mucopurulent secretion, which cannot be removed except with a probe and cotton. The external nose becomes congested and swollen as the disease progresses, and the eyes become sympathetically affected. As a complication, late in the course of the affection, the accessory sinuses may become involved.

The distress experienced by a patient with oedema is vastly in excess of that encountered in simple rhinitis vasomotor periodica (hay fever). The absolute despair of the victim is at times pitiable, and the inability to afford even a temporary relief is discouraging to the physician.

This affection appears chiefly in neurotic women and men of sedentary habits, between the ages of thirty and fifty, and sometimes in youths of fifteen to nineteen. From a careful investigation of the latter class of cases, the conclusion arrived at has been that the disease is sometimes associated with sexual perversion, and the success of the treatment which is recommended rather confirms this hypothesis. Ofttimes, however, an oedema is independent of the sympathetic nervous system, and is directly due to impeded circulation caused by pressure of new growths situated in the superior meatus, by hyperplasias, hypertrophies, and polypi. Ethmoiditis with earies in the vicinity of the sphenopalatine ganglia was found to be the cause in a case which had been considered a gouty nose. A constant symptom of rhinoedema seems to be an intensified desire to breathe through the nose, amounting almost to mania.

Several patients have told me that, maddened by the inability to breathe, they have rushed upstairs to get some water or ice, and the awful tension was for a few seconds relaxed by the exertion.

In other cases the shock of a cold douche on the spine has served the same purpose when alternated with a hot one.

The fact that a change of climate does not as quickly relieve cases of this kind as a radical change of the modus vivendi has led me to institute a course of treatment or training which is rapidly productive of good. I insist that these patients go to a regular gymnasium or have a teacher come to them and give progressive gymnastic exercises to put them in a profuse sweat twice a day, after which they take a warm bath, followed by a cold shower or plunge and a brisk alcohol rub. They must keep in the open air. Usually I advise walking ten squares and back, increasing a square a day, an hour after breakfast and luncheon. In other cases I prescribe the Sandow physical exercises, of which there are twenty-eight, supposed to exercise every muscle in the body, these to be done on rising and before dinner. If this is carried out, going to a gymnasium is unnecessary.

Now I come to the most important step in the treatment of this affection, and that is the use of the rectal sits douche with the nozzle in the centre of the cushion, by which the patient may wash the entire colon morning and night with four quarts of water in which is put
a spoonful of sea salt and sodium bicarbonate. In no way can venous stasis in any part of the body be so quickly relieved, and, as a treatment to benefit the portal circulation, it has no equal as an adjunct to exercise.

This mode of treatment, with a little strychnine and digitalis, will soon put the nasal mucous membrane in condition to resist monochloracetic acid without danger of a general slough taking place. In these cases cauterizing the nose with electricity or acid in the early edematous condition is hazardous in the extreme. All edemas are not the result of venous stasis or impediments to the return current, and it is difficult to conceive that in the nose a true impeded return might be established. Much more reasonable is the hypothesis that altered nerve function or vascular disturbance caused by a neighboring ethmoiditis primarily induces the dilatation and infiltration, which soon partake of the characteristics of a true edema.

While I do not consider that rhinœdema is a disease that may be isolated as an affection *per se*, I advance the term as a satisfactory word to illustrate a condition often occurring, by means of which we may etymologically differentiate a true edema from the numerous varieties of rhinitis, under which term our nasal affections are perhaps unwisely classified.

### CALIFORNIA CLIMATE AND CHRONIC DISEASES OF THE KIDNEYS.

**By WILLIAM H. DUKEMAN, M. D.,**

**LOS ANGELES, CAL.**

Next to the lungs, no organs suffer so seriously from the inclemency of the weather and undue dampness of the soil as do the kidneys. Next to overindulgence in a highly nitrogenized diet as a cause of renal diseases are exposure to cold, sudden changes in temperature, dampness of the soil, and improper clothing.

Whenever there exists a suspicion of disease of the kidneys, the patient must be most carefully watched and guarded against the above causative conditions.

The functions of the skin and of the kidneys are so closely allied that, by repeated chills of the former, with the accompanying contraction of the cutaneous vessels, there is produced a hyperemia or congestion of the renal vessels. The action of the skin being checked, there is an accumulation of waste material in the blood; the functional activity of the kidneys is thereby increased to rid the system of this accumulation of waste material, and the final result is the induction of organic renal disease.

In the great majority of cases, chronic Bright's disease is thus slowly and insidiously brought about. So imperceptibly does it establish itself that the patient and his physician are usually not awakened to the existing condition of affairs until there is a gradual failure of health.

No assignable cause being manifest, the thoughtful physician, not to be caught napping, makes a careful and searching urine analysis and a microscopical examination of the urine, when the nature of the malady may be at once revealed.

With this brief sketch of the causes of certain diseases of the kidneys we at once readily see that the starting point in the treatment is not to be directed point blank at the kidneys, but to remedy first the existing causative conditions.

The prevalence of Bright's disease in temperate climates is undoubtedly largely accounted for by the existing variable climatic conditions, and for a person so afflicted to remain in such a climate with crippled kidneys only hastens the end. By the avoidance of any acute attacks of congestion or inflammation on the once crippled kidneys by the removal to a warm, equable climate with a dry soil, the life of such patients will be materially lengthened and many complications and sequelæ avoided.

In some portions of southern California where there exists a sandy, porous soil, where the sun shines three hundred days of the year, and the patient can be outdoors nearly every day of the year; where the temperature rarely falls below 40° F.; where exists almost a perpetual summer; where almost every climatic condition exists to relieve the crippled kidneys of any undue work, not only will the living days of such patients be undoubtedly prolonged, but they will live in peace and comfort.

For the benefit of such patients as may desire to know the minor particulars as to clothing, etc., adaptable to this climate, I would say, they will require the same clothing precisely as they wear in a temperate climate. The main object is to keep the skin warm; and in this climate, although it never gets cold in winter nor very hot in summer, yet flannel underwear and fleecy hosiery should be worn the year round, as well as flannel nightdresses in which to sleep, as the nights are invariably cool enough for everybody to sleep under blankets.

While the invalid can be outdoors nearly all the daytime, the changes of temperature from morning to noon and from noon to nightfall can be easily guarded against by a little attention to clothing, so that the skin may never be chilled.

The mean annual humidity in this climate varies from seventy to eighty per cent.; but where the sun shines nearly every day in the year, the high percentage of moisture in the atmosphere is of very little consequence.

As to diet, one can very easily adapt himself to avoid a highly nitrogenized diet in this climate where there is an abundance of fruit and vegetables. Very little meat will be required, as one very soon learns that indulgence in a meat diet, even for the robust in this climate, is not necessary.
THE RADICAL CURE OF HALLUX VALGUS.*

By Russell S. Fowler, M.D.,
Instructor in Surgery in the New York Polyclinic; Adjunct Surgeon to the Brooklyn Hospital; Assistant Surgeon to the Methodist Episcopal Hospital; Consulting Surgeon to the Southern Dispensary and Hospital, New York.

Hallux valgus, or bunion, is the most important deformity of the toes. It consists in an outward deviation of the great toe from its normal axis. Just how this is caused is rather difficult to explain. Ill-fitting shoes are responsible in the great majority of cases. The changes present in an advanced case are contraction of the external lateral ligament of the metatarso-phalangeal joint of the great toe, relaxation and attenuation of the internal lateral ligament, shortening of the extensor tendon of the great toe, and an enlargement of the outer aspect of the head of the first metatarsal bone. The result of all these changes is that the great toe assumes a fixed position of abduction. It lies across the other toes, either above or below them. In those cases which have come under my personal observation, the great toe has always been on the extensor surface of the others. The sequence of events is as follows: The patient has worn, probably for some length of time, shoes which pressed upon the head of the first metatarsal. This causes an inflammation of the periosteum with proliferation of cells and new bone formation. The internal lateral ligament is attenuated by pressure from this new-formed bone. As a result of this increase in size and of the relaxation of the ligament the toe assumes an abducted position. This abduction becomes more and more exaggerated as the disease progresses. There is contraction of the external lateral ligament and also of the extensor tendon. An enlarged bursa may or may not be developed internal to the enlarged head of the first metatarsal. This bursa may become infected.

It is not, however, my present purpose to enter exhaustively upon the pathology and treatment of hallux valgus, but rather to describe a slight addition to the original procedure advocated by Professor George R. Fowler.† The history of the last case in which this operation was employed is as follows— one case is typical of the others:

J. McI., forty-five years of age, an engineer, had had a bunion on each foot for twenty years. These had always been somewhat painful. Seven years ago Dr. George R. Fowler operated upon the right foot at St. Mary’s Hospital. Since then the patient has had no trouble with that foot. At the present time the relationship of the parts is perfect. For the last few years the bunion on the left foot has been getting more and more painful. A few months ago the bursa overlying

Changes of Address.—Dr. Edmund W. Bill, to No. 24 West Twenty-fifth Street, New York; Dr. Edward F. Brennan, to No. 265 Alexander Avenue, New York; Dr. Charles J. Laflin, to No. 1545 Madison Avenue, New York; Dr. James P. McEvoy, to No. 10 East Twenty-eighth Street, New York.

* Read before the Brooklyn Pathological Society, October 12, 1899.
† Medical Record, 1889, No. 10, vol. xxxvi, p. 253.
the head of the metatarsal bone became inflamed, ruptured, and discharged a thin greenish material. For the past year the patient has been unable to work. Physical examination of the chest shows a rough systolic murmur at the apex. This case presented all the exaggerated features of a long-standing lesion. The enlargement of the head of the first metatarsal bone was extreme. The internal lateral ligament was much attenuated. The external lateral ligament was represented by a very much contracted fibrous cord. The extensor tendon of the great toe was much shortened. The operation in this case was performed September 21, 1899, by the following method:

The soft parts are transfixed with a slender-bladed knife between the great toe and its neighbor. The knife enters the sole of the foot half an inch proximally to the level of the metatarsal-phalangeal joint and emerges on the extensor surface at the same level and just external to the extensor tendon of the great toe. With a single sweep of the knife the soft parts are cleanly severed parallel to the long axis of the metatarsal bones and in the web between the toes. There is no danger of injuring the tendon if the technic is properly observed. The great toe is adducted, putting the contracted external lateral ligament upon the stretch. The joint is entered by severing this ligament completely. So far but two strokes of the knife have been used. The fingers of the left hand now grasp the great toe, and by using strong adduction dislocate it completely inward, so that the toe lies on the internal aspect of the first metatarsal bone. This procedure exposes the enlarged head of the first metatarsal. With a few strokes of the scalpel the fibrous tissue on its internal aspect is loosened and then pushed back with the handle of the scalpel. The soft parts are protected and a triangular-shaped piece of bone removed either by means of a metatarsal saw or a chain saw. This triangular piece includes the hypertrophied portion of the head and also a portion of the articular surface. The proper relationship of the joint is now reproduced. Should the deformity tend to recur, as is sometimes the case, on account of the contraction of the extensor tendon, it will be necessary to lengthen this tendon. There is no need of sectioning it completely, nor is any elaborate tendon operation necessary. The lengthening is preferably done at some distance from the site of the operation proper in order to avoid any possibility of infection in the tendon. Accordingly a half-inch incision is made over the course of the tendon some two inches distant from the angle of the original incision. Through this small opening the tendon is hooked up, identified, and drawn as far out of the wound as possible. With a fresh knife the tendon is cut halfway across at the uppermost available point. The same procedure is carried out from the other side of the tendon at a point half an inch lower down in its course. Traction upon the tendon thus treated results in lengthening it sufficiently to overcome any tendency to recurrence of the deformity. The tendon is replaced and its incised edges disappear beyond the level of the incision, which is closed by two or three fine silk sutures introduced from within outward to avoid skin infection. The primary wound is closed preferably with silk, as silk worm gut is apt to cause discomfort from its stiff ends pressing against the skin between the toes. No ligatures are necessary, as none but the smallest vessels have been cut. A small piece of gauze may be introduced to act as a drain should any serous oozing occur.

Separate dressings are placed upon the wounds. The parts are held in their proper relation by means of pads and two splints, one an internal and one a plantar splint. The entire foot is included in the dressing. If drainage has not been necessary, the wound is to remain untouched until the sutures are removed on the seventh day.

This procedure is essentially that devised by Professor Fowler, with this exception: one transfixion incision is employed. The accompanying lengthening of the tendon is done at a distance and not through the original incision. The success of the procedure has been, in my experience, both immediate and permanent.

MALARIAL INFECTION
AS A FACTOR IN CAUSING EYE DISEASE.

By PAUL TURNER VAUGHAN, B.Sc., M.D.,
HOT SPRINGS, ARK.

GLAUCOMA following Supraorbital Neuralgia of Malarial Origin was the title of an article in the New York Medical Journal of recent date, and after reading the article it occurred to me that some remarks dealing with the subject of eye complications in malarial infection would not be inappropriate in a journal having such a large circulation in the Southern States as the New York Medical Journal has.

Quite a number of invalids coming to this resort live in malaria-infected districts, and consequently it falls to the lot of the ophthalmologist here to treat rather frequently the various eye complications caused by malaria.

Dr. Jean Manuel Espada,* in writing of the evil effects caused by paludism or malarial infection, remarks: "In all countries that are essentially paludic, all or nearly all of the inhabitants are attacked with the disease in a greater or lesser degree. One has the characteristic color of the integuments, in another the digestion is weak; again, the liver or the spleen, or both at the same time, may be enlarged, while others are affected in different ways. Very rarely do we find a person who enjoys perfect health. If, occasionally, some one is seen who enjoys apparent health, there will always be something latent found in the constitution that indicates the working of the disease.”

After reading this extract it is not difficult to conceive then why a disease producing such a variety of symptoms and invading every tissue in the body should at times cause pronounced pathological change in the eye—it is only peculiar that a subject of such importance has not been thoroughly worked over by medical men in the South, where ample opportunity is presented for studying this interesting disease in all its phases.

The ocular manifestations of malaria differ according to whether they accompany an acute attack of fever or the malarial cachexia (Schmidt-Rimpler). The

* Journal d’hygiène, and reproduced by the Sanitarian.
most prominent symptom that I have observed in the latter class of patients is a noticeable variation in the visual power at different times. During the past eighteen months several cases exhibiting this symptom in a greater or lesser degree have come under my observation; in one case it was especially marked. At the initial examination, for instance, vision was equal to \( \frac{1}{20} \) in the course of two weeks it changed to \( \frac{1}{200} \), and then a reduction to nearly \( \frac{1}{2000} \) again occurred. Ophthalmoscopically there was no finding apparent sufficient to produce such a disturbance in vision. The papillae were somewhat enlarged, hyperemic, and the adjoining retinal portions were cloudy. The gentleman had never had syphilis, was not a hard smoker, and was very temperate in drink. He came from a malarial district and his vision improved immediately after I inaugurated a quinine treatment.

Sulzer \(^*\) calls special attention to this variation of the visual power at different times in persons with the malarial cachexia. He remarks that the visual field is intact or only slightly contracted concentrically; the color sensation remains normal; sometimes hemeralopia exists, and occasionally photophobia. This latter symptom I have never seen among my patients, but can well understand how it could be present. He also found ophthalmoscopically the “papilla optica swollen, of a dark-red color, and the adjoining retina opaque.” This agrees substantially with the findings in my case.

Poncet \(^\dagger\) attributes the discoloration of the papilla to the presence in the dilated capillaries of giant cells which contain pigment.

Gowers \(^\ddagger\) refers to singular paralytic symptoms which are met with in the course of malarial fevers or of the malarial cachexia, and especially in the latter of grave symptoms which are produced by obstruction of the cerebral vessels by pigmentary matter. This pigment matter is in all probability analogous to the pigment deposits referred to by Poncet.

Penno\footnote{Klin. Monatbl. f. Augenheilkunde, 1890, p. 236.} states that he has observed deposits of black pigment in the papilla optica and along the retinal vessels, while De\-pagn\footnote{De la rétine-choroidale pathol. Annales d’oculistique, vol. Ixxix, p. 291, 1878, and quoted by Schmidt-Rimpler.}e\footnote{Revue d’ophthalmologie, 1894, p. 385.}et reports thinning of the optic nerve.

Other observers have reported minute hemorrhages, especially in the peripheral portions of the retina (Schmidt-Rimpler). I have never observed these, but any one familiar with the various types of malarial poisoning will readily asent that hemorrhages are rather to be expected in certain varieties of this disease. This is especially true of the congestive types, but in these it is very difficult to obtain a satisfactory examination of the fundus within several days after the attack.

Another condition observed in malarial infection, and one which Sulzer often saw, is an infiltration of the vitreous. In writing of this condition he reports a case in which the patient became totally blind in both eyes within eight days. Finally, however, counting of fingers in close proximity was attained in one eye. In another case which he reports, of a similar nature, the use of quinine and residence for a time in the mountains produced complete recovery.

Poncet, from his studies with the microscope, is of the opinion that in cases of the above character the principal seat of the disease process is in the chorioid: he found here hemorrhages with cells containing pigment and varicose capillaries. This affection he described as “chorio-retinitis palustris” (Schmidt-Rimpler).

Another case which came under my observation last winter presented a very interesting train of symptoms, and was somewhat similar to the case reported in the article referred to above as appearing in the New York Medical Journal of several weeks since.

The gentleman had been sick for several weeks when I was called to see him. Twice during the past ten years he has suffered attacks of a similar nature to the one I was called to see him in, but neither of these attacks was as severe as the last one. The left eye was normal. Examination of the right revealed a marked degree of ptosis, conjunctiva very much congested, pupil dilated, cornea somewhat cloudy, a slight increase in intraocular tension, and vitreous opaque. The pain, which corresponded with the side of the head affected, was very intense. The attack was introduced by supraorbital neuralgia. All the symptoms appeared to become more aggravated at regular intervals, and during these exacerbations fever was always present. The patient was given iron and quinine; gradually the attacks ceased, the ptosis disappeared entirely, and the vision rose to what it was before the attack. After the attack subsided, ophthalmoscopically nothing abnormal was observed in the fundus other than a slight opacity of the vitreous; this, however, was not sufficient to prevent a thorough examination of the fundus.

According to Penno, the pupil is always dilated and the papilla hyperemic during an acute attack of fever. Sulzer also observed in this condition that the retina was apparently covered with a fine mist. Schmidt-Rimpler remarks that according to Sulzer this state produces a certain predisposition to disease of the macula which is induced by the action of reflected sunlight—similarly as it is also caused by direct sunlight. He (Sulzer) observed these affections in a number of soldiers who suffered from febris tertiana and who, while free from fever, made marches in the bright sunlight. The conjunctiva is often injected and even iritis may also occur (Schmidt-Rimpler).

In severe attacks of malarial fever amblyopia is not uncommon. An instance illustrating this fact
comes to me from a physician who is at present a patient of mine. He tells me that a patient of his who came from a malarial-infected district—the swamp lands bordering upon the Mississippi—during an attack of malarial fever suddenly became blind, but as soon as sufficient quinine could be absorbed to check the fever the amblyopia was recovered from.

Schmidt-Rümpel remarks that retrobulbar neuritis (Uthoff), optic-nerve atrophy, ptosis (Adelheim), and other muscular paralyses have been observed in intermittent fever; also that inflammatory processes—iritis, irido-chorioiditis, keratitis parenchymatoso, and a peculiar form of keratitis exhibiting radiating ulcers, developed probably from herpes cornææ, designated keratitis dendritica, and described by Val Milligen and Kipp—have been observed as occurring during intermittent fever.

In my case, above reported, the ptosis was especially marked—so much so, in fact, that even partial opening of the eye was impossible.

It is needless to refer to the supranasal neuritis of malarial origin. Every physician who has had any experience with malarial infection knows how readily this affection responds to quinine.

Therapeutical Notes.

For the Pruritus of Dentition.—The Gazette hebdomadoire de médecine et de chirurgie for September 24th ascribes the following to Besnier:

| R | Hydrochloride of cocaine | 2 grain |
| R | Bromide of potassium | 7½ grains |
| M | Distilled water | 130 |
| M | Glycerin | 150 |

For local application.

The Alkaline Dressing for Wounds.—Two French army medical officers, Dr. Augé and Dr. Casteret (Bulletin de l'Académie de médecine, August 10th; Lyon médical, November 19th), report favorably on sodium bicarbonate as a dressing for suppurating surfaces, stating that it causes the pain and inflammation to subside in a day or two and checks the suppuration. They say it does not in itself exert a germicidal action, but, by virtue of its alkalinity, strengthens the germ-resisting power of the tissues. They use a solution from two to four per cent, in strength, the water having first been boiled.

The Hypodermic Injection of Orthoform and Calomel in Syphilides.—Reformia médicale for November 14th attributes the following to Daouls:

| R | Vaseline | 15 grains |
| R | Calomel | 3 of a grain |
| M | Orthoform | 120 grains |

For hypodermic injection in syphilides.

The Treatment of Tuberculous Peritonitis. — Dr. Gabriel Mauzrange (Gazette hebdomadoire de médecine et de chirurgie, October 19th) speaks well of lactic acid, especially in children, for the relief of diarrhoea and the stimulation of the appetite. Adonis verticillatus as a diuretic and antipyrine in small doses for the hectic are lauded by Pribram, together with mercurial frictions. According to the author, creosote is specially indicated in cases where intestinal ulcerations exist, as it favors their cicatrization. But, generally speaking, he thinks that creosote and its derivatives (creosotal, etc.) may be used with advantage in all forms of tuberculous peritonitis. It may be administered hypodermically after Burelureau's method, avoiding large doses, or according to M. Sevestre's formula:

| R | Glycerin | of each | 1,500 grains |
| M | Creosote | | 60 |

To be taken by teaspoonfuls.

Or it may be combined with hydrochlorophosphate of calcium, or given in wafers, according to M. Kopp's formula:

| R | Creosote | of each | 15 grains |
| M | Benzoin | | 30 |
| M | Powdered vegetable charcoal | | 90 |

Divide into ten wafers.

Injections of artificial serum are sternly proscribed by the author as being apt to provoke extension of the tuberculous process.

The Treatment of Epileptic Attacks.—Carrière (Reformia médicale, November 16th), after recommending the employment of the usual measures and precautions, says that all therapeutic efforts are useless, and that when stertor appears the sleep of the patient should be respected and he should be left to awaken without intervention. But if the aura is repeated and the patient's morbid condition confirmed, he recommends his removal to a darkened, quiet room and the administration of the following elixir:

| R | Sodium sulphate | 300 grains |
| | Senna leaves | 300 |
| | Honey of mercurialis | 600 |
| | Glycerinated water | 3,150 |

M.

Note.—Honey of mercurialis occurs in the Swiss, French, and Belgian pharmacopoeias. It is made by boiling various proportions of Mercurialis annua (a euphorbiaceous plant) in water and adding honey.

Injections for Angioma.—Blaschko (Münchener medizinische Wochenschrift, No. 16, 1899; Lyon médical, August 20th) recommends the following formula:

| R | Perchloride of iron | of each | 15 grains |
| | Chlorella of zinc | | 15 |
| | Hydrochloride of cocaine | | 1 grain |
| | Distilled water | | 150 grains |

M.

From half to a whole Pravaz syrupful to be injected every two or three days.

For Constipation with Scanty and Defective Bile Secretion.—The Therapist for November 15th gives the following formula:

| R | Arsenious acid | 1 grain |
| | Corrosive sublimate | 1 |
| | Powdered ipecacuanha | 2 grains |
| | Calomel | 16 |

M. Make into fifteen tablets. One or two to be taken daily.
THE NEW YORK MEDICAL JOURNAL.
A Weekly Review of Medicine.

Published by
D. APPLETON AND COMPANY.Edited by
FRANK P. FOSTER, M.D.

NEW YORK, SATURDAY, DECEMBER 16, 1899.

THE GENERAL PROFESSIONAL WORK OF A LUNATIC ASYLUM.

It may be questioned if in any department of medicine there has been greater improvement of late years than in the management of the insane. Conspicuous among the institutions in which this advance has been displayed are the hospitals maintained by the State of New York. The time is not so far back when, save for the work of an occasional enthusiastic psychiatrist—work in which he too often met with obstruction where he had a right to expect cooperation—the affairs of lunatic asylums were administered like those of petty principalities having practically nothing to do with the rest of the world, and those who had charge of them seemed to have drifted into the intellectual doldrums. But there has been an awakening of which the medical profession may well be proud. Now no stone is left unturned in following up every idea that promises to better the condition of the insane or to throw light on the various forms of mental disease. Without professing to point out any frequent connection between mental alienation and physical disease having its seat elsewhere than in the organ of mind, we may say that physical ailments occurring in the insane ought to receive as much attention as those of the sane. We believe that at the present time they do in our State hospitals and in many others. A notable example is that of the St. Lawrence State Hospital, the twelfth annual report of which has just been published.

The report of the medical superintendent, Dr. William Mabon, shows that the daily average number of patients during the year ending September 30, 1898, was 1,389.66, representing 718.08 men and 671.58 women. Upon these patients surgical operations were performed in sufficient number to show the amount of attention to their physical ailments that we have alluded to. Venesection was performed twice, and lumbar puncture twenty-four times. Perhaps these two procedures were resorted to on some indication intimately connected with the patients' mental condition, but in addition to them there were five operations (radical) for hernia, three for disease of the vermiform appendix, three for phimosis, two each for the removal of hemorrhoids, for hydrocele (by aspiration), for removal of the tonsils, and for varicocele, and one each of amputation of a toe, of amputation of a finger, of abdominal section for peritonitis, of intestinal anastomosis, of exsection of the sciatic nerve, for deep cellulitis, for hydrocele (by removal of the sac), for abscess of the liver, of iridectomy, of paracentesis of the pleura, of paracentesis of the peritoneum, for perforating ulcer of the foot, for removal of the Fallopian tube and ovary, for strabismus, and for tuberculous disease of the knee. The superintendent tells us that for the most part these operations were performed by members of the hospital staff, but that in a few exceptional instances two of the practitioners of Ogdenburg, Dr. Madill and Dr. Bell, were kind enough to operate. He tells us, too, that Dr. Bell corrected errors of refraction in three hundred of the patients. Furthermore, a dentist visited the hospital every two weeks and had an average of sixteen patients under his care all the time. This leads us to suggest that in the St. Lawrence Hospital and in the other State hospitals it might be well to appoint a dentist on the staff, and let him have at least the benefit of official recognition in return for his services.

Of course, this operative work does not represent the entire non-psychiatric practice of the hospital, but it serves as an index to it. The superintendent's report touches upon several other matters of medical interest concerning which investigations are in progress. The results of those relating to the secretions of epileptics are to be embodied in a report that is soon to be published in the Archives of Neurology and Psychopathology. As these researches have been carried on in collaboration with the State Pathological Institute and with other hospitals for the insane, they will doubtless be found to be of great value. The members of the medical staff of the St. Lawrence State Hospital are to be credited with a high degree of that professional enthusiasm which is almost the sole impulse of medical progress.

PRESERVATIVES AND DYES IN ARTICLES OF FOOD.

Along with the fear of deleterious effects from the preservatives and coloring matters that are often added to certain articles designed to be taken into the human stomach, there is in most persons a natural antipathy to "doctored" products, as was shown by the recent outcry about "emblamed beef." And yet it seems that the community itself is in great measure to blame for the practice of adding to articles of food, beverages, preserves, pickles, confectionery, etc., substances intended either to preserve them or to give them an inviting
appearance. At least, this appears to be the case in England, if we may judge from some of the testimony lately given before a committee of the Local Government Board as reported in the *Lancet* for November 25th. For example, in the matter of ham and bacon from the United States and Canada it was contended by some of the witnesses representing the Liverpool Provision Trade Association that, if the preservation of such products rested on the use of salt alone, so much of it would have to be used that they would be too salt to suit the popular taste and, moreover, that they would be apt to get slimy; hence the prevalent practice of packing them in borax, which was wiped off when they reached England, not only was harmless, but insured a more acceptable food supply for the people. So, too, in the case of preserved fruit, jams, and the like, it was maintained that the public would not buy them unless they were of a desirable color; in particular, preserved white cherries were unsalable unless they were colored red. We do not think that this particular prejudice concerning the color of preserves prevails here in New York, but it must be admitted, we fear, that our people are set upon having their preserved peas and their pickles of a vivid green.

In spite of the strong statements of one physician as to the complete innocuousness of boric acid taken in daily amounts far in excess of those that would ever be taken into the stomach with preserved food, the medical testimony, so far as the hearing had proceeded, was almost unanimously in favor of prohibiting the use of preservatives, except sugar and salt, especially in milk to be taken by infants, although several of the witnesses were inclined to admit that their addition in not more than the required quantity would be harmless, except in the ease of milk for children. A general feeling was evinced that all products to which chemicals had been added should bear a label informing the purchaser of such addition, but it was not generally insisted upon that the label should show the amount of preservative contained in the product; the New York and Pennsylvania requirement that the mere fact of chemical preservation should be stated seemed to be all that most of the witnesses would urge, and the trade representatives declared themselves quite ready to conform to such a regulation.

It may be unwise to decree the absolute prohibition of chemical preservation and coloring, but there can be no doubt that the use of chemicals and dyes ought to be regulated quite sharply. It was pointed out by some of the witnesses at this hearing that the preservative used was sometimes simply thrown into a mass of the food, and not properly mixed with it, whereas the desirability of its equable diffusion was too evident to be questioned. It was further suggested that a workman in a preserve factory, for instance, was apt to be careless about the ordinary precautions to be observed in the art of preserving if he knew that his shortcomings were to be rectified by the use of a chemical, and the result of his carelessness might be an inferior product quite independently of the fact of chemical preservation. These points seem to us well taken, and we have no hesitation in declaring that the employment of chemical preservatives and dyes should be regulated most stringently.

THE PREVENTION OF DENTAL CARIES.

There is an impression prevalent in European countries that Americans are peculiarly liable to early decay of the teeth. We have long been of the opinion that the notion had no firmer foundation than the fact that a great amount of dentistry was done in the United States, a fact due to the attention paid by most of our people to the care of their teeth and to the excellence of our dentists. It has now been made plain that in one other country, Great Britain, early decay of the teeth takes place with such frequency as to have led a careful and competent observer, James Cantlie, M.B., F.R.C.S., to present the subject with great seriousness before the Section of State Medicine of the British Medical Association (British Medical Journal, September 2d), and, after the discussion that followed, to propose a resolution to the effect that, in view of the early decay of the teeth prevalent in Great Britain, the council of the association be requested to appoint a committee of not fewer than three persons to inquire into the subject and to report upon it to the council in twelve months from the date of their appointment. The resolution was carried unanimously.

In his paper Mr. Cantlie recognized the excellence of the art of dentistry as practised in his own country and in America, saying that, so far as mechanism was concerned, there was little more to be done. But he expressed the wish that the dentists should “look a little further afield,” and tell how to rear a child so that the teeth while yet within the dental sacs, before their eruption, might be allowed to grow to the greatest perfection. “If,” he said, “dentistry is to aspire to its highest ideal, it must not be content with merely repairing or removing damage done”; it must tell us the reasons of the early decay of children’s teeth and show us how to prevent it. Mr. Cantlie mentions two theories only to dismiss them as unworthy of serious consideration. One is that of the preponderant early development of the brain in the present generation.
whereby the teeth have been thought to be robbed of a good part of the nutrient material that should go to them; the other is that the jaws do not now reach their proper growth, so that there is not room for perfect dental arches and the teeth are crowded together and thrown into such irregularity of arrangement as to afford many a lurking place for decaying matter. The first of these theories perhaps has little to sustain it; it is fanciful or at best only plausible. The second, we are inclined to think, is more entitled to weight. At all events, we think Mr. Cantlie is in error in dismissing such a theory on the ground that the changes mentioned are assumed to have taken place in our own generation, an assumption “contrary to natural law.” We do not understand that anything of the sort is assumed, and we question if it can be shown that, as Mr. Cantlie says, “the generation immediately before us had fairly good teeth and well-shaped jaws.”

The November number of the *Dental Cosmos* has a strong editorial article entitled Tooth Caries and Public Health, which gives the gist of Mr. Cantlie’s argument and points out some of its defects, among others that of ignoring bacterial influence in producing dental caries. The writer professes the complete readiness of dentists to give information as to the prevention of premature decay of the teeth, if only they possessed it. They are still in quest of that information, just as we are seeking for the prevention of cancer, for example; when they have found it they will give it to the world, for they, like all other workers in medicine, have constantly in mind the prevention of disease.

**REMOVAL OF THE ACCESSORY THYROID GLANDS.**

The functional sufficiency of a comparatively small portion of a system of organs is a striking illustration of the perfection of the organism. Perhaps it is nowhere better exemplified than in the case of the accessory thyroid glands. Dr. Capobianco and Dr. Mazzocchi, of Naples (Giornale internazionale delle scienze mediche, 1899, Nos. 8 and 9; Centralblatt für innere Medizin, November 18th), find that, if only one of the four glands is left in the operation of parathyroidectomy, the fatal result that follows the removal of all of them is prevented.

**DEAFNESS DUE TO MUMPS.**

In our issue for September 9th we gave a brief résumé of an article on this subject that had appeared in the Gazette des hôpitaux. Our article ended as follows: “The pathogenic remains obscure, but most authors think there is a sanguineous effusion into the labyrinth. Treatment is of no avail as regards the power of hearing, but the vertigo may be mitigated by means of quinine.” Dr. Edmund D. Spear, of Boston, takes a more favorable view. He calls our attention to an article of his published in Burnett’s *System of Otology, Rhinology, etc.* in 1893, in which he spoke of the importance of recognizing deafness as a sequela of mumps, and suggested the attempt to cut the disease short by rest in bed and the subcutaneous use of pilocarpine. With this drug, he says, many cases of effusion into the labyrinth have been cured. He intimates that its use in mumps would lead to earlier resolution and tend to prevent complications.

**MAJOR-GENERAL WOOD.**

The medical profession will receive with the greatest satisfaction the news that General Leonard Wood, who began his military career in the medical corps of the army, has been made a major-general of volunteers and also appointed military governor of Cuba.

**THE DISTRICT OF COLUMBIA ANTI-VIVISECTION BILL.**

We learn that Senator Gallinger’s bill purporting to “regulate” experiments on animals in the District of Columbia has been introduced again. That being the case, it behooves physicians throughout the country to besist themselves in opposition to a proposed measure which, if it became a law, would put practically unlimited power for evil into the hands of persons inimical to a most important means of prosecuting medical research.

**THE ACADEMY OF MEDICINE’S PORTRAIT OF DR. METCALFE.**

The correspondence between Dr. T. Gaillard Thomas and the president of the New York Academy of Medicine, published elsewhere in this issue, relates to a most graceful act on the part of Dr. Thomas, that of presenting to the academy a portrait of Dr. John T. Metcalfe, who for many years was recognized as one of the ablest of New York physicians. He has now retired from practice and is living, we understand, at Cold Spring on the Hudson.

**BILI AS A NEUTRALIZER OF RABIES VIRUS.**

It seems that among the manifold properties of the bile is that of neutralizing the virus of rabies. M. Vallée (Annales de l’Institut Pasteur, June; Centralblatt für innere Medicin, December 2d) finds that the inoculation of animals with a mixture of equal parts of the virus and the bile of a rabbit that has died of rabies, or that of a healthy rabbit, does not kill them, but it confers on them no immunity.

**TETANY ATTRIBUTED TO EXPOSURE TO THE SUN.**

In the British Medical Journal for November 25th Herbert Fox, M. B., reports a case of tetany which he could not attribute to any other cause than exposure to the sun, an aetiological factor which, as he remarks, is at least unusual.

**THE MODERN MASTERY OF DIPHTHERIA.**

The superiority of our present means of treating diphtheria has seldom been more forcibly illustrated than in a case reported by J. A. R. Smith, M. B., of the Melbourne Hospital, in the October number of the In-
tercolonial Medical Journal of Australasia. Intubation was employed and accomplished all that could have been expected of it, but there was such an extensive bronchial exudate that tracheotomy was required for its removal. A photograph of the cast shows that it extended well into the lungs, and, with the tendency to fresh exudation present, it is doubtful if the patient would have been saved after all, but for the use of antitoxine, which was given by the intravenous method.

THE EARWIG.

There seems to be some justification for this as the popular name of the insect Forficula auricularis (not the little centipede so called in the United States), as was remarked by M. Pautet (Lyon médical, November 23rd) recently when he showed at a meeting of the Lyons Society of the Medical Sciences a specimen of it that he had removed from the external auditory canal. It had not perforated the membranes tympani.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported for the two weeks ending December 11, 1899:

The Canadian Medical Association.—The following appointments of committees are announced: A committee having charge of the preparation of suggestions for a Canadian addendum to the new British Pharmacopæia, Dr. T. D. Reed, Dr. A. D. Blackadar, Dr. J. G. Adami, Dr. R. Wilson, Dr. H. Hervieux, and Dr. A. D. Bazin, of Montreal; Dr. A. Marois, of Quebec; Dr. H. B. Small, of Ottawa; Dr. J. M. MacCallum and Dr. J. T. Fotheringham, of Toronto; Mr. J. E. Morrison, Mr. T. E. W. Lecours, Mr. W. H. Chapman, and Mr. A. Roberts, together with the president and the general secretary. A committee to consider and report upon the best means of dealing with the consumptive poor, Dr. P. H. Bryce, Dr. W. Oldright, and Dr. E. J. Barrick, of Toronto; Dr. R. W. Powell, of Ottawa; Dr. J. A. Williams, of Ingersoll; Dr. J. G. Adami and Dr. H. A. Lafleur, of Montreal; Dr. J. D. Lafferty, of Calgary; and Dr. H. H. Chown, of Winnipeg. Publishing committee, Dr. A. D. Blackadar, of Montreal; Dr. H. B. Small, of Ottawa; and Dr. J. L. Davison, Dr. W. A. Young, and the general secretary (Dr. F. N. G. Starr), of Toronto.

The Eastern Medical Society of the City of New York.—At the annual meeting, on Friday evening, the 8th inst., the following officers were elected for the ensuing year: President, Dr. Abram Brothers; vice-presidents, Dr. J. Gutman and Dr. A. Hymanson; secretary, Dr. R. Abrahams; treasurer, Dr. J. Barsky; chairman of the committee on ways and means, Dr. H. Siff; chairman of the committee on ethics, Dr. E. K. Browd; trustees, Dr. H. Illooy, Dr. L. J. Ladinski, and Dr. H. Levien; committee on admission, Dr. S. Mossesdon, Dr. R. Hlochner, Dr. M. Girsdansky, Dr. C. Goodman, and Dr. George I. Miller.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending December 8, 1899:

**Small-pox—United States.**

- Washington, D. C. Nov. 25-Dec. 2 — 2 cases.
- Dixon, Ill. Dec. 3 — 125.
- Shreveport, La. Nov. 25-Dec. 2 — 1 case.
- Chelsea, Mass. Nov. 25-Dec. 2 — 3 cases.
- Six places in Michigan. Nov. 25 — Reported.
- New York, N. Y. Nov. 25-Dec. 2 — 2 cases.
- Cleveland, Ohio Nov. 17-Dec. 2 — 1 case, 1 death.
- Portsmouth, Va. Nov. 25-Dec. 2 — 3 cases, 1 death.

**Small-pox—Foreign.**

- Ghent, Belgium, Nov. 4-18 — 3 deaths.
- Rio de Janeiro, Brazil, Oct. 22-Nov. 3 — 200 cases, 123 deaths.
- Bombay, India, Oct. 23-Nov. 7 — 7 cases.
- Madras, India, Oct. 23-Nov. 3 — 1 death.
- Mexico, Mexico, Nov. 12-19 — 1 case, 1 death.
- Moscow, Russia, Oct. 28-Nov. 4 — 1 case.
- St. Petersburg, Russia, Nov. 4-11 — 9 cases, 5 deaths.
- Warsaw, Russia, Nov. 4-11 — 9 cases.

**Yellow Fever—United States.**

**Yellow Fever—Foreign.**

- Rio de Janeiro, Brazil, Oct. 23-Nov. 4 — 6 cases, 3 deaths.
- Havana, Cuba, Nov. 22-29 — 11 cases, 8 deaths.
- Santiago de Cuba, Cuba, Nov. 16-22 — 1 case.

**Cholera.**

- Bombay, India, Oct. 23-Nov. 7 — 2 deaths.
- Calcutta, India, Oct. 1-21 — 33 cases.

**Plague—Foreign.**

- Trieste, Austria Nov. 4 — 1 death (sailor on Ottoman Liner Polis Mytilini).
- Bombay, India, Oct. 25-Nov. 7 — 165 deaths.
- Calcutta, India, Oct. 1-21 — 134 cases.
- Kurrachee, India, Nov. 4 — 3 cases.
- Asuncion, Paraguay, Oct. 7-24 — 10 cases.

The Medical Society of the State of New York.—The president, Dr. Willis G. MacDonald, has appointed the following business committee, to which all communications concerning papers to be presented at the next annual meeting, on January 30, 1900, to February 1, 1900, should be sent: Dr. Wendell C. Phillips, No. 350 Madison Avenue, New York; Dr. Henry L. Eisner, Faye Park, Syracuse, New York; and Dr. Chauncey P. Biggs, No. 17 East Street, Ithaca, New York.

The Buffalo Academy of Medicine.—At the last quarterly meeting, on Tuesday evening, the 5th inst., it was decided to establish a section for the study of diseases of the eye, ear, nose, and throat. On Monday evening, the 11th inst., a meeting was held for the purpose of electing officers and arranging a programme for the ensuing year. On Tuesday evening, the 12th inst., there was a general discussion on personal experience with new drugs, and Dr. Allen A. Jones read a paper on The Relation of Indicanuria to Secretion of Hydrochloric Acid.
The St. Louis Medical Society.—At the last regular meeting, on Saturday evening, the 9th inst., the subject for discussion was a paper by Dr. C. Shattinger, entitled A Demonstration of Cephalometry.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 2 to December 9, 1899:

DE Witt, CALVIN, Lieutenant-Colonel and Deputy Surgeon-General, will proceed by the first available commercial steamer sailing from New York to Havana, if one sails before a transport.

LAWSON, GEORGE B., Acting Assistant Surgeon, United States Army, will proceed to San Francisco for duty.

W. H. RAYMOND, Henry L., Major and Surgeon, United States Volunteers. The sick leave of absence granted him is extended one month.

WILCOX, TIMOTHY E., Major and Surgeon, United States Army, is detailed as a member of the examining board convened at the Army Building, New York city, vice WATERHOUSE, SAMUEL M., First Lieutenant and Assistant Surgeon, relieved.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending December 9, 1899:

CARPENTER, D. N., Assistant Surgeon. Ordered to the Boston Navy Yard.

DUNBAR, A. W., Passed Assistant Surgeon. Detached from the Resolve and ordered home to await orders.

Promotions.

DICKINSON, D. Promoted to medical director.

HARMON, G. E. H. Promoted to medical inspector.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioners and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending December 7, 1899:

MEAD, F. W., Surgeon. Granted leave of absence for one day.

PERRY, T. B., Passed Assistant Surgeon. Relieved from duty at New York and directed to proceed to Baltimore for duty and assignment to quarters.

WERTZENBACHER, C. P., Passed Assistant Surgeon. To rejoin station at Wilmington, North Carolina.

SMITH, A. C., Passed Assistant Surgeon. To proceed to New York and report to Surgeon L. L. Williams (Immigration Depot) for special temporary duty. To proceed to Hamburg, Germany, for duty.

BLUER, RUPERT, Passed Assistant Surgeon. To proceed to Genoa, Italy, for duty.

SPRAGUE, E. K., Passed Assistant Surgeon. To proceed to Antwerp, Belgium, for duty.

GREENE, J. B., Passed Assistant Surgeon. Relieved from duty at Boston and directed to proceed to New York and report to Surgeon L. L. Williams (Immigration Depot) for special temporary duty.

TAMB, S. R., Assistant Surgeon. To proceed to Savannah Quarantine Station (Georgia) for temporary duty.

GRUBB, S. B., Assistant Surgeon. To proceed to New York and report to Surgeon L. L. Williams (Immigration Depot) for special temporary duty. To proceed to Havre, France, for duty.

HOODY, W. C., Assistant Surgeon. To report at Washington for special temporary duty and then to rejoin station at New York. Relieved from duty at New York (Stapleton) and directed to report to Surgeon L. L. Williams (Immigration Depot) for special temporary duty. To proceed to Southampton, England, for duty.

CoRPut, G. M., Assistant Surgeon. Upon being relieved from duty at Baltimore to report at Washington for special temporary duty; then to proceed to New York, reporting to Surgeon L. L. Williams (Immigration Depot) for special temporary duty.

THOMpsoN, F. J., Assistant Surgeon. Relieved from duty at San Francisco and directed to proceed to the San Francisco Quarantine Station for duty.

Goldsborough, B. W., Acting Assistant Surgeon. Granted leave of absence for two days.

Society Meetings for the Coming Week:

Monday, December 18th: New York Academy of Medicine (Section in Ophthalmology and Otolaryngology); New York County Medical Association; Hartford, Connecticut, Medical Society; Chicago Medical Society.

Tuesday, December 19th: New York Academy of Medicine (Section in General Medicine); Buffalo Academy of Medicine (Section in Pathology); Ogdensburg, New York, Medical Association; Syracuse, New York, Academy of Medicine; Medical Society of the County of Kings, New York; Baltimore Medical Academy of Medicine.

Wednesday, December 20th: Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark).

Thursday, December 21st: New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Massachusetts, Society for Medical Improvement (private); Medical Society of City Hospital Alumni, St. Louis; Atlanta Society of Medicine.

Friday, December 22nd: New York Clinical Society (private); New York Society of German Physicians; Yorkville Medical Association, New York (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

Saturday, December 23rd: New York Medical and Surgical Society (private).

Births, Marriages, and Deaths.

Married.

ARCHINARD—VIENNE.—In New Orleans, on Tuesday, December 12th, Dr. John J. Archinard and Miss Madeleine Vienne.

FURMAN—HENDRICKSON.—In Bay Shore, Long Island, on Thursday, December 7th, Dr. Isaac Furman and Miss Laura B. Hendrickson.
Letters to the Editor.

THE SENSE OF PREVIOUS EXISTENCE.

To the Editor of the New York Medical Journal:

Sir: In the New York Medical Journal of November 11th Dr. Ellis brings up the interesting subject of what Scott calls "a strange sense of preexistence." I can not agree with the doctor that this is a mental condition "seldom if ever described in medical literature.

First, in what is not strictly speaking medical literature, Dr. Oliver Wendell Holmes, in the Atlantic Monthly for 1857, and afterward, in 1882, in the Autocrat of the Breakfast Table, writes: "All at once a conviction flashes through us that we have been in the same precise circumstances as at the present instant once or many times before?" He then goes on to give explanations of this phenomenon, the best being "that the coincidence of circumstances is very partial, but that we take this partial resemblance for identity, as we occasionally do resemblances of persons. The apparent similarity may be owing perhaps quite as much to the mental state at the time as to the outward circumstances.

Professor James, in his Principles of Psychology, in the chapter on Memory, writes: "There is a curious experience which every one seems to have—the feel-
The patient, by calling his physician to testify, waives the privilege. Also, the patient's attorney waives for him when he calls the physician as a witness and states that as the patient's attorney he waives the privilege of the statute. It is also held that a patient, by permitting a physician to testify regarding privileged matters, either as his own or his opponent's witness, waives the privilege. It is advisable to state, however, in this regard that a physician, whenever placed upon the witness stand by another than his patient, for the purpose of disclosing privileged matter between himself and that patient, should, in justice to that patient, inform the court that the matter he is asked to divulge was learned by him in the course of his professional attendance, and that he desires to submit the question to the court whether he may, consistently with the confidence reposed in him by the patient and with his own professional integrity, disclose such confidential matter. A case similar to the one supposed, in which the physician disclosed matter that should have been carefully guarded, went to the supreme court of Michigan several years ago, and Justice Conley, in delivering the opinion of the court, took the opportunity to censure both the physician and the commissioner who permitted the evidence to be received, in the following words: "Every reputable physician must know of the existence of this statute (protecting confidential communications); and he must know from its very terms, as well as from the obvious reasons underlying it, that it is not at his option to disclose professional secrets. A rule is prescribed which he is not to be 'allowed' to violate; a privilege is guarded which belongs to him, but to his patient, and which continues indefinitely, and can be waived by no one but the patient himself. What was done in this case may have been thoughtlessly done; but if a physician is found disposed to violate both the law of the land and the precepts of professional ethics by making such a disclosure, and if counsel invite him to do so by their questions, the commissioner, in the case of so plain a disregard of the law to the prejudice of a third party, may well decline to be an instrument of the wrong." *

In case of a criminal prosecution instituted by the patient, who is prosecuting witness, he will be deemed to have waived his privilege, and the physician who attended the patient for the injuries inflicted by the accused will be properly permitted to testify. Thus, in a rape case where the criminal act was committed upon a child, and the prosecution was inaugurated by the child's parents, and the child and her mother testified at the trial regarding the criminal act and the injuries thereby inflicted, the supreme court of Nevada was of the opinion that the parents by their conduct showed a desire to waive the protection of the statute, and that the physician's evidence was therefore properly admitted. [4]

But whether or not the patient, by taking the witness stand in a civil suit and testifying regarding his health, waives his privilege of objecting to the evidence of his physician as to the condition of his health at the time referred to in his testimony is a question upon which the decisions are not in harmony. It has been observed that in several States the statute extending the privilege to the patient expressly provides that when the patient voluntarily testifies he will be deemed to consent to the examination of his physician. In States having such a statute there can be no doubt that the patient, by testifying concerning matter within the knowledge of his physicians, in law authorizes them to make a full disclosure relative thereto, but whether his testifying will have such effect in other States is seriously doubted. In the court of common pleas of New York, however, Justice Pryor held that the plaintiff, who testified minutely and circumstantially to the effect of a blow upon her physical condition, and disclosed to the jury without reservation all the ill consequences of the injury to her health and comfort, thereby waived the privilege of objecting to the evidence of the physician who had attended her for the particular injuries. Almost contemporaneous with this case is one from the supreme court of Iowa, in which the plaintiff testified minutely regarding the health she enjoyed previous to the accident upon which the suit was based, in such a way as to justify the belief that she was an unusually vigorous and healthy woman. The defendant then offered the evidence of the physician who had attended the patient occasionally during the time referred to in her testimony, but the court denied that the plaintiff by her evidence had waived her privilege of objecting to the disclosure proposed, and therefore refused to permit the physician to testify. The authorities seem to be uniform upon the proposition that where a patient at the trial testifies regarding his condition at a certain time physicians who attended him at another time than that covered in his testimony can not be permitted to testify regarding the patient's condition at such other time contrary to his objection. In the case of Butler vs. Manhattan Railway Company, the plaintiff, who was pregnant, upon attempting to board a car upon the elevated railroad, was struck a severe blow in the side by the iron gate as it was forcibly closed by the brakeman, producing a miscarriage. At the trial the plaintiff testified regarding her physical condition subsequent to the accident, whereupon the defendant attempted to prove by the physicians who had attended the patient previous to the accident what her condition was during that period, but the court refused to permit the disclosure offered. It also seems well settled that when a patient is attended by several different physicians at different periods, and he calls one physician to testify to his condition during the period in which that physician treated him, he does not thereby waive his privilege as to the other physicians. Thus, where the patient, who had been injured in a railroad accident, first employed Dr. A., but before recovering discharged him and employed Dr. B., it was held that by calling Dr. B. to testify regarding his condition he did not waive his privilege as to Dr. A., and that Dr. A. could not be placed upon the witness stand by the defendant to testify, con-

¶ Hope vs. Troy and Lansingburg Ry. Co., 40 Hun, 338.
But "Upon Grattan late the attending party, to facts learned while attending him professionally.* And so, when a patient called physicians to testify to his condition previous and subsequent to a certain period, he did not thereby waive his privilege to object to the evidence of another physician, who had attended him during the intervening period, regarding his physical condition during such intervening period.† But when two or more physicians attend a patient at the same time the question of whether, by calling one of them to disclose his condition, he waives his privilege as to the others is one upon which the decisions are conflicting. The court of appeals of New York holds that by such an act he does waive his privilege of objecting to the evidence of the others. The court says: "We think that a construction of the statute which permits a patient who has been attended by two physicians at the same examination or consultation to call one of them as a witness to prove what took place or what he learned, thus making public the whole interview, and still retain the right to object to the other, is unreasonable and unjust, and should not be followed. The waiver is complete as to that consultation when one of them is used as a witness."‡ Upon the other hand, the supreme court of Iowa in a recent case held that a patient, by placing on the stand one of several physicians who had attended her, presumably at the same time, did not waive her right of objecting to the evidence of the others as privileged.  

The question of whether the privilege, having once been waived in a given case, may ever again be asserted, is also one in which there is conflict of authority. In the case of Grattan vs. Insurance Company,[1] the New York court of appeals held that a party having waived the privilege at one trial could claim it upon a new trial of the same case; but the same court, in the case of McKinney vs. Grand Street, etc., Railroad Company,[2] decided four years later that the patient having once consented to the disclosure of privileged information could never again assert his privilege regarding the subject of his former waiver. The supreme court of Michigan, in a late case,[3] in passing upon practically the same case, reviewed the decisions of the New York court and, after expressing its preference of the rule laid down in the Grattan case, held that a privilege having been waived at one trial might be asserted at a new trial of the same case.  

That a patient fully and completely waives all privilege as to matters connected with the physician's treatment of him when he sues the physician for alleged malpractice in such treatment can not be justly doubted. "To establish a contrary rule," said Justice Gavin, "would be most manifestly unfair."‡ But a rule of similar justice does not prevail where a physician sues a patient to recover for the value of his professional services, and the patient interposes an answer containing a general denial. In such a case the patient does not waive his privilege, and the physician may not testify as to any information protected by the statute.* He may, however, testify that he is the family physician, and that he attended the patient, giving the dates and number of such visits made, and mentioning the examinations, prescriptions, and operations, but he may not describe them if the patient objects.†

(To be continued.)

**Pith of Current Literature.**

**Ichthylol in Corneal Ulcers.**—Dr. B. F. Travis (Medical Herald, November) says that his attention was called to the use of ichthylol in ophthalmological work about eighteen months ago in an extract from a paper written by a French writer, who had used it, and was advocating it as a remedy for trachoma. He at once applied it according to that writer's method in an old case of trachoma in which there were corneal ulcers and pannus. The improvement in the ulcers was so marked that he decided to test its merits as a remedy for corneal ulcers, regardless of their cause, and he has used it in a great many cases, some of them very severe, and his results have been phenomenal. After experimenting with the drug in different strengths he now applies about a thirty-per-cent. solution, diluted with glycerin and distilled water, ordering weaker solutions for home use. Ichthylol, he says, has no bad effect upon healthy epithelium, even in the stronger solutions. It is very painful for about one minute, but the instillation of a one-per-cent. solution of hollonnae a few minutes before the application of ichthylol is made renders it much more comfortable to the patients. The author prefers hollonnae from the fact that it is itself an anti-septic and is not contraindicated in corneal ulcers as is cocaine.

Among the great number of local remedies in use, ichthylol has given the best results in the writer's hands. Atropine is used for its anodyne effect and because it lessens the liability to iritis. Eserine is indicated instead of atropine in small, sluggish ulcers unattended by active symptoms, or in cases of deep ulcers near the margin of the cornea. In strumous cases the usual constitutional should be also employed.

**The Relation of Leucocytosis to Appendicular Inflammation.**—Dr. Maurice Richardson (American Journal of the Medical Sciences, December), in a general paper on appendicitis, says that from a hundred cases of appendicitis at the Massachusetts General Hospital Dr. R. B. Greenough has drawn the following conclusions in regard to the relation of leucocytosis to appendicitis. The paper is to be published later by Dr. Greenough: 1. Leucocytosis may be considered to be a fairly constant symptom of appendicitis. 2. The presence or absence of leucocytosis, or the degree of leucocytosis, without other data, is not sufficient to determine the local condition of the appendix and its surroundings. 3. In a series of cases the degree of leucocytosis corresponds roughly with the degree of temperature, but in

individual cases great variations are found. 4. The degree of leucocytosis, when considered in connection with the duration of the attack, is of considerable assistance in the diagnosis of the local condition. 5. A high leucocytosis (above twenty thousand) on the first or second day of disease suggests general peritonitis. 6. A low blood count (below ten thousand) after the first week, if accompanied by severe symptoms, indicates general peritonitis, and is of grave prognostic significance; but if accompanied by mild symptoms, denotes a mild catarrhal process or well-walled-off abscess which has become subacute in character. 7. A high leucocytosis (above twenty thousand) after the first week or ten days may be taken to indicate a local abscess.

Hygienic Treatment of Nocturnal Enuresis.—Stumpf (Bulletin de thérapeutique, November; Lyon médical, November 26th) recommends that the child should sleep with the head lower than the pelvis, thus creating a mechanical obstacle to the passage of the urine, which no longer irritates the urethral sphincter. Stumpf had treated successfully twelve children and an adult by this method, which has also proved efficacious in two rebellious cases at the Institute for Deaf-Mutes at Wurzburg. The duration of the treatment is about three weeks, after which the normal position may be resumed.

Tumor of the Pituitary Body.—Dr. G. L. Walton and Dr. F. E. Cheney (Boston Medical and Surgical Journal, December 7th), in a paper on this subject, arrive at the following conclusions: 1. Congenital peculiarities in growth resembling those of acromegaly, but occurring in otherwise healthy individuals, may point to structural defect of the pituitary gland, a defect sometimes furnishing the starting-point for a new growth later in life. 2. The occurrence of pituitary tumor without definite symptoms of acromegaly does not necessarily disprove a connection between this organ and this disease, for the persistence of even a small amount of healthy gland tissue is sufficient fairly to carry on the function of the pituitary body. 3. The combination of general symptoms of new growth with optic atrophy and loss of temporal field of vision makes the diagnosis of pituitary tumor almost certain. 4. Hemiachromatopsia is not necessarily of central origin.

The Difference in Labor between Savage and Civilized Women.—Dr. Archdall Reid (British Medical Journal, October 14th) thinks that the difference between savage and civilized women, as regards labor, may be explained in a manner which seems feasible, and is at any rate in accordance with modern theories of heredity. We know that, while children tend to inherit the peculiarities of their parents, they tend also to vary somewhat from them. Thus, for example, big or fair people tend as a rule to have big or fair children; but each child, generally speaking, is bigger or smaller, fairer or darker, than the parent. It follows that women with large or small pelvis tend to have daughters with a like peculiarity also; and that people, who at birth had large or small heads, tend to transmit this peculiarity also. Now savage women, generally speaking, have large pelvis, and bear children with small heads, hence the ease of their labors. When, however, a savage woman varies from her parent in such a manner as to have a small pelvis or to bear a large-headed child, her life is endangered. A really difficult labor re-

quiring surgical aid of course to her means death. Among the lowest nomadic savages, a labor even as difficult as is normal among civilized races would be fatal. The race is thus strictly purged, generation after generation, of all narrow hips and large heads, and the right proportion between head and pelvis is from age to age secured.

But with the rise in civilization greater care is bestowed on lying-in women; those who would otherwise have died are preserved, and thus the just proportion between head and pelvis is gradually lost. First, natural labors become difficult, though not impossible. The severity of the labor exhausts the woman, and makes her so ill, and liable to septic infection from tears, abrasions, and crushings, that under more savage conditions she would perish. In any case she is incapacitated from labor or movement for some days. In the highest civilization, such as our own, labors are so difficult that many of them are terminated only by surgical interference. How important this surgical interference is, every skilled obstetrician may judge for himself. Let him think how many small-hipped women and large-headed children he saves annually. Suppose they perished, would not the average difficulty of labor among the circle of his patients be appreciably ameliorated in the next generation? What happens in his own circle happens in the world at large. Here, then, the author thinks we have the reason why the labors of civilized women grow increasingly difficult as our surgical skill improves, and an increase of difficulty which to some small extent explains that increase of instrumental interference which Professor Sinclair so grievously deplores. About the end of the twenty-first century Dr. Reid thinks it not improbable that another gynecologist will denounce the obstetricians of his day, and point out that, while their grandfathers used forceps in only about seventy-five per cent. of their cases, degenerate contemporaries use them in at least ninety-nine per cent. In the not very remote future it seems to him probable that normal labor will be the exception, not the rule. Injuries will then be very numerous, and gynecologists very busy.

Unusually Delayed Development of Vaccine Pustules.—Dr. E. T. Duke (Maryland Medical Journal, October 28th) records an extraordinary case of delayed development of vaccine pustules. He vaccinated a man in February, 1899, but the vaccination apparently did not take. In the following August the subject was daily on the beach in bathing costume. Within a few days after being exposed to the intense heat of the sun a vesicle formed at the point of vaccination, the patient's arm became inflamed and swollen, and following this a scab formed, which remained for three weeks, and being removed left a well-marked cicatrix.

Hemophilia.—Dr. G. W. Wagner (Physician and Surgeon, September), in a paper on this subject, concludes from a careful study of the literature that: 1. Hemophiliacs make blood rapidly, the cause of which fact is undetermined. 2. There is a tendency to plethora of the smaller vessels, especially of the capillaries. 3. The deficiency of oxygen in the blood is one of the main reasons for its slow coagulation. 4. The narrow lung space, at least in some cases, is a factor in the deficient oxygenation of the blood (whence the author suggests that in future the capacity of the lung space be carefully noted). 5. Apparently the best remedy to control the hemorrhage is oxygen, either by inhalation or contact. It acts in two ways, causing greater rapidity
in the coagulation of the blood and also causing the nuclei of the endothelial cells of the capillary wall to swell and thus narrow the lumen of the vessel.

**Antitoxine Statistics in Diphtheria.**—Dr. A. J. Tonkin (Lancet, October 21st), as the result of observations on two hundred cases of diphtheria treated at theMontserrat Fever Hospital, full statistical tables of which are given, concludes as to the use of antitoxine that:

1. The general mortality rate is reduced. The mortality for cases treated during the first three days of illness is reduced to about three per cent. and that for all other cases about twelve per cent. 2. Laryngeal cases treated early are markedly affected for the better, the tracheotomy mortality is very much lessened. 3. There is less need for tracheotomy if treatment is begun early. 5. All ages and both sexes are equally affected. 6. The chances of nephritis are lessened. 7. When treatment is begun early albuminuria may not appear, and if appearing, will probably not be severe, and will disappear soon. 8. Paralysis is lessened for cases treated on the first and second days of the illness. The paralytic mortality is much reduced. 9. Extension of disease to the larynx and parts below was not noted after injection of antitoxine. 10. The only disadvantage noted after its use was a slight discomfort for a few days from utricarial rashes and pains in the joints in a small percentage of the cases. The conclusions arrived at may be taken as a plea for early diagnosis and early antitoxine treatment.

**Mixed Diet in Typhoid Fever.**—Dr. Grynitsky (Vratch, September; St. Paul Medical Journal, December), in a paper read before the Wilna Medical Society, said that Botkin, Manassen, and Tchdnovsky are advocating the mixed diet. He then reported his own cases. From December, 1898, to June, 1899, there were admitted a hundred and fifty-two patients with typhoid fever to the Wilna city hospital. Of these, eighty were put on a mixed diet. The regimen was as follows: 8 a.m., milk or tea and white bread were given; 10 a.m., a glass of milk; at 2 p.m., a piece of herring to excite appetite, followed by meat soup, boiled meat, or beefsteak; at 6 p.m., chicken broth, and at 8 p.m., milk with or without bread. Coffee was served every other day, and wine occasionally. The results were gratifying: indeed, as a rule, the patient’s tongue was clean, delirium rare, no intestinal hemorrhage, no relapses, and convalescence was rapid, the patient looking well from the time he left the hospital. The only had results were: Marked tympanites, one; severe vomiting, one; delirium, one; pain or discomfort in abdomen, one. Of the fifty-two patients treated to a restricted diet, the results were as follows: Localized peritonitis, one; middle-ear complications, one; and in one, delirium, four; meningitis, two; relapses, four; convalescence tedious, strength returning slowly. The death-rate was in the same proportion.

**Static Electricity for Sprains.**—Snow (Journal of Electro-therapeutics, October; Charlotte Medical Journal, November) says that electro-static treatment for sprains produces very prompt and satisfactory relief when there is no rupture or laceration of the soft parts. Even in other severe cases such treatment will afford more relief than any other. The method of treatment is as follows: The patient is seated upon the platform with the negative pole grounded, the balls of the prime conductors being in contact: the affected joint being encased in a sheet or bandage of block tin, closely molded to the surface. With one cord connect the patient with the negative pole of the machine. Now start the machine and gradually open the spark gap until either the muscles are thrown into slight contractions or the patient complains of discomfort from the treatment. At this point, allow the machine to run for from ten to twenty minutes. At the end of the treatment, upon removing the metal bandage, the surface will be found wet and the patient will be able to move the joint with freedom and without pain, if the treatment has been correctly followed. The patient who has been treated by this method will be greatly relieved and the conditions much improved. This is due to the prompt restoration of equilibrium—the general effect of electro-static currents in congested and painful conditions.

**Urotropin in Chronic Inflammation of the Seminal Vesicles.**—Dr. J. M. Thompson (Boston Medical and Surgical Journal, November 16th) says that thus far in his experience urotropin has had the most notable and salutary effect in this affection. As a rule, when first seen, these patients call one’s attention to the urine, which is nearly always abnormal in color, high in specific gravity, and more or less turbid. A deranged nervous system is not uncommon, while the neurotic element frequently betrays itself. Such patients, too, are likely to suffer from either periodical or persistent phosphaturia, which urotropin dissipates as if by magic. The turbidity so common in these cases, whether due to the pathological deposit which escapes backward from the vesicles or to involvement of the prostate (what is known as "prostatorrhoea"), to a catarall condition of the deep urethra or to the presence of bacteria, disappears after the administration of urotropin.

It is not uncommon to find among those who have suffered from the pains and discomforts which only the gonococcal causes that after all symptoms have subsided for a time the discharge returns copious and free, yet unaccompanied by the other symptoms characteristic of the first stage. Naturally, such patients are likely to be extremely debilitated and nervous; their urine is either neutral or alkaline. Upon questioning them, one will discover that the treatment which they have followed included the daily use of an antacid, like sodium bicarbonate, which for the first few days contributes to the patient’s relief, but when continued beyond the acute stage, or rather beyond the time when such treatment is indicated, by prolonging an abnormal (alkaline) reaction of the urine, keeps such normal constituents as phosphates, carbonates, etc., in a state of precipitation, a condition that must in time act as a mechanical irritant to the urethral mucous membrane and provoke what may be termed a "phosphatic urethritis." If urotropin is ordered in seven-and-a-half-grain doses morning and evening, a most happy effect will be noticed in about forty-eight hours, and, unlike the effect produced by a mineral acid, of a permanent character.

Recently the author tried urotropin in two cases—the patients aged sixty-four and fifty-seven respectively—with enlarged prostate. Both had been obliged to use a catheter for years, except at times when the symptoms abated sufficiently to enable them to void their urine naturally. At such times as the catheter was not a necessity the urine appeared normal, beyond the pres-
ence of small flocculi and comma-shaped shreds; whenever the catheter was likely to be employed the urine took on a murky, cystitic look, and soon became alkaline and foul-smelling. The usual subjective symptoms returned, and life became a real burden. Both patients were under observation at this stage, when it was expected that the catheter might be required at any moment. In order to test the virtues of urotropin, each patient was put on seven grains and a half of the drug three times a day. The effect was most gratifying, for the urine cleared up rapidly, and the subjective symptoms disappeared gradually. The urine still remains in a satisfactory condition, and both patients report that urotropin has enabled them to enjoy the longest period of happiness that has fallen to their lot for years.

The Treatment of Gouty Tophi with Piperazin.—Dr. Giovred (Gazzetta degli ospedali; Revista de Medicina y Cirugia Practicas, October 25th) says that the general manifestations of gout are improved by the prolonged internal administration of piperazin; but this substance was injurious against gouty concretions situated in the tendon of the peroneus longus—three quarters of a grain of piperazin dissolved in half a cubic centimetre of water were therefore injected into the concretion. The patient felt an acute burning pain, which was relieved by the application of ice. On the second day some diminution of volume in the concretion was observed. The injections were repeated till ten had been given, and were followed by complete disappearance of the tophi. Dr. Giovred thinks that intra-articular injections of piperazin might be efficacious in gouty arthritis.

Non-ecbolic Hemostatic Remedies.—Professor Bossi, of the University of Genoa (Riforma medica, July 10th), sums up a series of papers with the following conclusions: 1. There persists in obstetric practice, especially among midwives, an abuse of ergot, which it is a rule now ought not to be administered so long as the uterus is not emptied; this abuse is caused particularly by ignorance, and by the scanty employment of the non-ecbolic uterine hemostatics. 2. Obstetric practice should be enriched with the greatest possible number of non-ecbolic hemostatics for administrations during pregnancy and the puerperium, and not by extending the use within given limits and under special guarantees even to midwives of the employment of ergot, which is best by considerable dangers. 3. To hydrastis canadensis and hamamelis virginica we can now add stypticin and acetanilide as non-ecbolic hemostatics. 4. Experiments on animals have proved stypticin to be less toxic than the fluid extract of hydrastis and not provocative in the pregnant state of any disturbances worthy of note. Moreover, as in animals (gravid bitches and rabbits), so in women, it has not shown any ecbolic action, but rather possesses calminative properties. 5. Acetanilide has been demonstrated by clinical experiments as a uterine hemostatic with special properties of quelling the contractions. 6. Although the hemostatic action on the uterus of stypticin and acetanilide is not proved to be superior to that of hydrastis, these remedies nevertheless are most useful in practice, either in alternation with hydrastis and hamamelis or in substitution for them. 7. By the rational subdivision of obstetrical metrorrhagias into (a) metrorrhagia of pregnancy with a possibility of avoiding its interruption, and (b) metrorrhagia previous to, during, and after parturition, where the interruption is inevitable, we can usefully prescribe as follows: a, in the first group, a mixture of non-ecbolic hemostatics (hydrastis, hamamelis, stypticin) with uterine sedatives (piscidia, opiates), acetanilide excepted; b, in the second group, a mixture of hydrastis, hamamelis, stypticin, recurring, however, when necessary, to the use of sugar and quinine. The use of this mixture of remedies is authorized by the consideration that in obstetric practice hemorraghe demands nearly always urgent and efficacious intervention. The author refers to the following formulae. For group a:

- Fluid extract of hydrastis canadensis,
- Fluid extract of hamamelis virginica,
- Tincture of piscidia erythrina, of each 150 grains;
- Fluid extract of viburnum prunifolium, Sydenham's laudanum ...... 30 grains.

M.

Of this mixture not less than ninety drops should be administered at a time in half a tumbler of water, and according to the indications this dose may be given up to thrice in twenty-four hours. A five-grain tablet of stypticin may be given at the same time.

In group b:

- Fluid extract of hydrastis,
- Fluid extract of hamamelis,
- Stypticin

M. Administer from a measured phial not more than one hundred drops for a dose, repeating if necessary to three times in the twenty-four hours.

When it is necessary to reinforce the uterine constrictions without incurring danger of tetanus of the womb, the author recommends from 750 to 3,000 grains of sugar in from 3,000 to 7,500 grains of water, to be sipped as a beverage. Or bisulphate of quinine may be prescribed in a dose of a grain and a half to be taken every hour.

An Antidote for Poisonous Bites.—Dr. S. T. A. Kent (Charlotte Medical Journal, November) recently read before the State Medical Society of Virginia a short communication on a remedy for snake and spider bites. It is a moss known locally in Halifax and Pittsylvania Counties, Virginia, as “snake moss.” A knowledge of its virtues was obtained by Dr. Rawley White, of Virginia, from the Indians in the early years of the present century. It has, however, not hitherto attracted much professional attention. It has been identified for the author by Messrs. Parke, Davis & Co. as “one of the allies of the ferns, viz., one of the club mosses, Selaginella apus (Linn.).” It is found only in moist, shady places. The method of using the plant is to take as much as can be packed in a large thimble, about half a drachm in weight, macerate it thoroughly with an ounce of sweet milk, and swallow a portion of the moss, binding the balance to the wound. The author is, however, skeptical as to the share of the local application in the cure. It seems to give prompt relief from pain, to alleviate shock, and to rapidly remove swelling and all local and constitutional symptoms. The author records from among others two cases in human beings and
one in a dog of bites by a copperhead moccasin in which these effects were promptly manifested. It would seem as though the differences between the venoms of different reptiles were those of activity and intensity only, and not of degree, and consequently it is surmised that a remedy useful against the bites of certain reptiles would probably prove useful with modifications against others.

Carbonic-acid Gas in Heart Disease.—W. Ewart (Medical Record, September 9th; Medical Times, December) says that mitral stenosis and pain are greatly relieved by the inhalation of carbonic-acid gas for thirty seconds, the patient's bowels to be kept very free and the use of cardiae tonics to be restricted. There is not only a relief of pain, but greater freedom of respiration, with an improved state of the pulse and the appearance generally. Carbonic-acid gas acts as an anaesthetie, and also as a stimulus to the muscles of respiration, and a continued use of the inhalations has the effect of gradually removing the dilatation. By the ordinary treatment it is difficult to influence mitral stenosis, but carbonic-acid gas has always improved and often restored the patient to a condition of comfort.

Fish as Conveyers of Tuberculosis.—The French correspondent of the Medical News for December 2d says that at the Society of Biology, on October 7th, Nicolas and Lesieur told of the results they obtained by causing young fish to eat sputum known to contain tuberele bacilli. After seven months the fish were killed and the bacilli were found to be present in every organ of their bodies which was examined. The muscular portions of these fishes were given to guine-pigs, and in the nodules and abscesses which subsequently formed in the bodies of these pigs tuberele bacilli were readily demonstrated.

Temporary Contraindications to Vaccination.—Pediatricis for November 15th condenses from a recent number of the Presse médicale the following observations: At the Maternités de l'assistance publique of Paris, the rule is, not to vaccinate newborn infants weighing less than twenty-five hundred grammes (five pounds and a half). In infants with active erythema of the nates vaccination is postponed. A little later there may appear a formal contraindication—eczema. Whether on head or body, local or generalized, moist or dry, it should at once excite the attention of the physician. The danger is the appearance of supplementary vaccine pustules upon the diseased areas. Experience has shown that the risk is far from imaginary. Vaccine eruptions have appeared with great violence on ezcematous skin, the virus being conveyed by the child's or nurse's fingers, by clothes, etc., and being easily inoculable upon a raw surface. Only in times of small-pox epidemic should we disregard such contraindications.

A Hydatid Cyst in the Femoral Canal.—Dr. Frederick Edge (British Medical Journal, November 18th) records the case of a patient sent to him with a lump in the left groin, situated over the saphenous opening, lobulated, firm, and presenting no impulse on coughing. It had been increasing in size and was rather tender. The diagnosis was one of irreducible omental femoral hernia or lipoma coming from the femoral canal, and, as the lump was growing and causing pain, he determined to remove it.

A sac was met with and opened, when about a dozen daughter cysts escaped. The sac was dissected out and found not to enter the femoral canal, so that the hydatids were not deposited in herniated omentum, but in cellular or lymphatic tissue.

The Antenatal and Intranatal Factors in Neonatal Pathology.—Dr. J. B. Ballantyne (Journal of the American Medical Association, November 10th), in a paper read before the Columbus meeting, gives the following summary of his conclusions:

"From all that has been said above, it is clearly evident that if the characters of the diseases of the newborn infant are to be understood it is essential that account be taken, not only of the facts that the infant's organism has just passed through a period of trauma-tism and is passing through one of readjustment to meet new requirements, but also that during the nine months of intra-uterine life which precede birth it may have been the sphere of morbid processes which have left their impress on it. It may come into the extra-uterine environment already diseased or malformed or predisposed to some pathological development. Like pregnancy, neonatal life is an epoch which has a physiology in many respects peculiar to itself, and which borders very closely on the pathological, tending very easily to pass over into it. In a certain sense the ordinary vomiting of pregnancy is to the uncontrollable form as the ordinary "physiological" jaundice of the newborn is to pernicious jaeterus neonatorum. Further, just as every woman brings with her into her pregnancy the results of her past pathological history, so the newborn infant brings with him, out of his antenatal life into his neonatal existence, the effects of any morbid processes which may have attacked him in utero. In this way the pathology of pregnancy and the maladies of the newborn infant are both invested with peculiarities. The peculiarities, therefore, of neonatal diseases are not inexplicable, but are the direct outcome of the action of the antenatal and intranatal factors on the organism at this period of life."

Injections of Normal Saline Solution in Mushroom Poisoning.—Dr. Delobel (Presse médicale, September 30th; Treatment, November 9th) was summoned to a man, aged fifty-two years, who had eaten a mushroom omelet, and found the patient covered with cold, clammy perspiration, breathing stertorously, and moaning pitifully from time to time. He trembled so violently that his bed shook under him: he was extremely cold; the pupils were dilated ad maximum: the pulse was feeble, almost imperceptible, and exceedingly slow, averaging 28 per minute. The patient had not vomited or had any action of the bowels, and there was suppression of urine. Considering that four hours had passed since the patient had eaten the mushroom omelet, Dr. Delobel thought that the end was near. However, he gave the man two hypodermic injections of atropine sulphate and ten injections of one cubic centimetre each of sulphuric ether: hot-water bottles were placed in the bed next to the patient, and two hundred cubic centimetres of a strong infusion of black coffee containing twenty cubic centimetres of rum were given by the mouth.

Presently the situation changed for the worse: the tremors ceased entirely; the patient lay motionless on his back; the pulse dropped to 24. At this critical moment a thousand cubic centimetres of artificial serum
were injected slowly under the skin of the thigh with a Roux's syringe holding forty cubic centimetres. The change which came over the patient almost immediately was remarkable. The pulse became strong and beating, increasing at the same time somewhat in frequency; when counted at intervals of fifteen minutes, its rate in a minute was 24, 28, 32, 40, 60 respectively. In the evening, before Dr. Delobel left his patient, the pulse rate had risen to 70 beats.

While this improvement in the heart's action took place, the respiration lost its Cheyne-Stokes character and became again regular; the temperature rose to normal. The next morning the patient had entirely recovered, and he went to work as usual on the following day.

The doctor examined some of the mushrooms that were left, and found that some were edible and some poisonous. The poisonous fungi, according to the description given by the author, were Agaricus phalloides and Boletus luridus.

Magnesium Sulphate in Tropical Dysentery.—Dr. F. A. Rouget, of Port Louis, Mauritius (British Medical Journal, November 18th) records the comparative results of the treatment of dysentery in the prison hospital by ordinary methods and by sulphate of magnesium. His results are as follows: Out of a total of forty-one cases in four months and a half treated by ordinary measures, six being severe and thirty-six mild, three severe cases died, two recovered, and one was discharged from hospital on the expiration of sentence, not improved; while twenty-eight mild cases recovered, and seven were discharged not improved. With the sulphate of magnesium treatment, however, the results were as follows: In ten months and a half fifty-six cases were treated, fifteen severe and forty-one mild. There were no deaths, but the fifteen severe cases recovered, as did thirty-nine mild ones, while two mild ones were discharged improved on expiration of sentence. The author says that the sulphate of magnesium was administered in doses of from a drachm and a half to two drachms, with ten minims of aromatic sulphuric acid and some cinnamon water and syrup. The result of the treatment was in all cases without exception remarkable. In from eighteen to thirty-six hours the dysenteric stools entirely disappeared; soft, yellowish faces were passed instead, and in a few days the cure was complete. During convalescence a powder composed of salicylate of bismuth, fifteen grains, and benzo-naphthol, ten grains, was given three times daily, to which three or four grains of Dover's powder were sometimes added.

In addition to this treatment, says the author, too much attention can not be paid to the diet, which should essentially be a milk diet. Any deviation from it is likely to materially interfere with recovery, and in not a few instances relapses occurred among the cases under his care owing to his Indian patients eating rice and curry.

Gelatinized Serum in Purpura Haemorrhagica.—The forms of haemorrhage in which gelatin has been recommended are many. Dr. Arcangeli, of Rome (Semaine Médicale; Treatment, November 9th), adds records of the successful use of a two-per-cent. gelatin in normal saline solution by injection into the subcutaneous abdominal tissue in cases of purpura with recurrent epistaxis and hemmorhage from the gums. The patients were young girls, aged thirteen and ten years. The dose employed was, in the first case, two injections of twenty cubic centimetres each, and in the second two injections of fifteen and ten cubic centimetres respectively, administered with twenty-four hours' interval.

A Red Coloration of the Faeces Simulating Blood.—Dr. Alfred H. Carter (Lancet, November 23rd) records three very interesting cases—one, an old man suffering from chronic valvular disease of the heart and febrile toxemia in connection with cystitis; another, a case of typhoid fever; the third, one of acute pneumonia. In all these cases the stools were of a golden-brown color, a streaky red color, closely resembling blood, being observed on the upper surface. Cotton pads, moreover, were stained till they bore strongly the appearance of blood. Close examination showed that the red streaks were due to the breaking up of a red layer on the upper surface, and that this coloration occurred on placing some of the golden-brown feces in a clean vessel, exposing it to the air, with repeated agitation. A careful examination by Dr. MacMunn, spectroscopic and chemical, failed to give evidence of blood. Dr. MacMunn concluded his report as follows: "I regret that I had not more material to work upon, but from the foregoing reactions the following conclusions are justified: 1. That no blood in an amount to cause a trace was present. 2. That no bilirubin or biliverdin was present. 3. That the pigment coloring the feces red was closely related to sterobilin (the normal pigment), though differing from it in some slight particulars. (I believe the difference is due to the incompletely metabolized condition in which it was excreted.) 4. That the feces at first contained the chromogen of the pigment, which on exposure to the air became converted into the corresponding pigment."

Dr. Carter points out that while only reasonable care is required to distinguish altered blood from the darkened stools of those who are taking bismuth, charcoal, or eating large quantities of meat, a red pigmentation resembling unaltered blood in the stools is of sufficient interest to demand notice, especially in view of the clinical importance of the latter phenomenon.

**Massage Treatment (Thure Brandt) in Diseases of Women.** By Dr. Robert Ziegenspeck, Professor of Gynecology and Obstetrics at the University of Munich. Authorized Translation by Dr. F. H. Westphal, Attending Physician of the Norwegian Lutheran Deaconess Hospital. With Seventeen Illustrations. Chicago: Published by the Author, 1899. Pp. 3 to 263.

On late years, since the novelty of operative gynecology has somewhat worn off, there has been an attempt made to introduce into the treatment of low-grade pelvic inflammations the methods of hydrotherapy and massage, especially the latter, which have proved to be so valuable in the relief of general disease. Every thoughtful gynecologist must realize that total hysterectomy is not an ideal procedure, and many patients return after so-called conservative and partial operations in a condition in no way improved by the surgical intervention. So, too, the majority of the subjects of so-called "pus tube" are sterile, the tube containing only sterile débris. This thickened and
chronically inflamed tissue is, of course, a place of lowered resistance and may at any time give entrance to a fresh infection, but, on the other hand, any one who has had a considerable autopsy experience will testify to the existence of many cases of chronic pelvic inflammation and adhesions which have given the patient no distress. The fact that so many of these cases run a subacute or chronic course has given rise to an attempt to obtain a cure of the milder types by local massage and general treatment. So far, the acceptance of the idea has not been widespread; few of the more influential gynecologists have taken more than a passing interest in the subject, and the expenditure of time required to produce a permanent cure, added to the high cost of the process, has greatly militated against its adoption. Ziegenspeck is one of those who have followed in the footsteps of Thure Brandt, the chief exponent of the method, and this translation of his book will be valuable to those who have not had access to the original. The volume contains a very detailed account of the various processes and manipulations to be used in the treatment of diseased annexe, and will be most welcome to those who seek to effect permanent cures in gynaecological cases.

This small volume has been written to explain the causes and nature of the disease whose characteristic is a low-grade inflammation of the tissues closely surrounding the teeth, and to give some idea of the importance to the general practitioner of a practical knowledge of the disease. It certainly fulfills this task in a most complete manner.

This is a most thorough exposition, both historical and practical, of the subject of interstitial gingivitis, which has evidently been the subject of much careful investigation by the author. Especially noteworthy are the photomicrographs with which the volume is profusely illustrated, showing all the different pathological stages of the disease. The printing and binding are excellent and the book can be confidently recommended.

This pamphlet is the result of a collective investigation instigated by the Soochow Missionary Association with a view to determine the extent of the evil produced by the smoking of opium. Almost all the replies show that the habit is on the increase, and that it tends to degrade its devotees and render them incapable of mental or physical labor. The remedies proposed include the prohibition of the growth of the poppy in India, an industrial revolution not likely to take place.

This small volume is one of a class by itself, in the consideration of which the purpose for which the book is written must always be kept in mind. It is written for the author's own classes in practical histology and physiology, and is not therefore intended for general circulation, except perhaps among teachers of the subjects treated. The part on histology is less original and less suggestive than the remainder, perhaps from the nature of the subject. The remaining sections, on chemical physiology and experimental physiology, besides offering a clear, condensed outline of the elementary course they cover, contain many hints from the point of view of the experienced teacher and practical laboratory worker. Special attention may be called to the simple physiological apparatus supplied to each student and the methods of furnishing power and chronographic currents for each desk. In the field in which it is to be used, as a practical elementary class book, the work is an excellent one.

The subject of the pathology of yellow fever has been a difficult one to unravel, and, unfortunately, its discussion has of late become to some extent polemic and personal rather than cool and scientific. The author of this monograph was one of the first to isolate from the blood an organism which he considers as the cause of the disease. The scientific world has never taken kindly to his ideas on the subject, and the connection of the organism with yellow fever has not generally been looked upon as specific. He reports excellent results following the protective inoculation of patients with attenuated cultures.

This is a small volume intended as a guide to nurses and surgical dressers in the preparation of dressing and the sterilization of the hands, the instruments, and the patient's skin. It is well suited for that purpose.

The author advocates the early use of both a dilute watery solution of the tincture of iodine and a moder-
ate dose of sodium iodide. The tincture of iodine, he says, is much more efficacious than the salts of iodine, and is especially valuable when associated with the local application of a white-precipitate ointment to the chancre or the cutaneous lesions. The treatment lasts from six to eight months, but in bad cases it may have to be resumed if any tertiary symptoms appear.

**SOME OF THE DANGERS OF ACUTE PHARYNGEAL ABSCESS OBVIATED BY THE USE OF A NEW TROCAR.**

By George C. Gage, M.D.,

Assistant Surgeon, New York Eye Infirmary.

Several cases of suffocation from pus entering the larynx during the opening of acute pharyngeal abscesses, although the children were placed in the prescribed forward-recumbent position, have recently come to my notice. These have forced me to the conclusion that this danger can only be obviated through the use of a safe trocar in emptying the abscess through the mouth; then the danger of suffocation by pus entering the larynx may be avoided.

The point of this trocar has been made cone-shaped so as to prevent any leakage; a guard ferrule has also been placed half an inch from the trocar point, which prevents its being pushed into tissues beyond the abscess wall. The hypodermic point admits of easy entrance, with no cutting edge to wound vessels.

In using the instrument, a mouth gag or cork is first placed between the molar teeth; then the left forefinger is carried down upon the abscess, and, using this as a guide, the trocar point is passed into the abscess with the right hand. The curve of the trocar adapts itself to the shape of the tongue. In case the pus should be too thick to flow readily, close the clamp on the rubber tube and apply suction at the distal end of the trocar by squeezing the bulb; the pus will then make its appearance down in the glass bulb. If the pus is thin, the trocar can be used without either tubing or bulb by disconnecting the instrument in the centre; there will then be a short trocar for evacuating either a periton-
sellar or retropharyngeal abscess.

47 West Forty-ninth Street.

**Miscellany.**

A Pre-Listerian Travesty of the Germ Theory.—The National Medical Review for November quotes the following curious dialogue from The Devil on Two Sticks,
by Foote, published in the year 1768, and reprinted by
William Miller in the British Drama, London, 1894:

"Dr. Hellebore: Brethren and students, I am going
to open to you some notable discoveries that I have made
respecting the source, or primary cause, of all distem-
pers incidental to the human machine. And these,
brethren, I attribute to certain animallike, or piscator-
ous entities, that insinuate themselves through the pores
into the blood, and in that fluid sport, toss and tumble
about, like mackerel or codfish in the great deep. And
to convince you that this is not a mere gratis dictum,
an hypothesis only, I will give you demonstrative proof.
Bring hither the microscope. (Servant enters with
microscope.) Doctor Last, regard this receiver. Take
a peep.

"Dr. Last: Where?

"Dr. Hellebore: There. Those two yellow drops
there were drawn from a subject afflicted with the jaun-
dice. Well, what d'ye see?

"Dr. Last: Some little creatures like yellow flies,
that are hopping and skipping about.

"Dr. Hellebore: Right. Those yellow flies give the
tinge to the skin and undoubtedly cause the disease.
And now for the cure! I administer to every patient
the two and fiftieth part of a scruple of the ovaria or
eggs of the spider; these are thrown by the digestive
powers into the secretory; there separated from the al-
imentary, and then precipitated into the circulatory;
where, finding a proper nidus or nest, they quit their
torpid state and vivify, and upon vivification discerning
the flies, their natural food, they immediately fall foul
of them, extirpate the race out of the blood, and restore
the patient to health.

"Dr. Last: And what becomes of the spiders?

"Dr. Hellebore: Oh, they die, you know, for want of
nutrition. Then I send the patient down to Bright-
helmstone, and a couple of dyes in the salt water washes
the cobwebs entirely out of the blood."

The Solidification of Hydrogen.—The Druggist's
Circular for November says that one by one the elements
which a generation ago were known only as "perma-
nent" gases have been reduced to more tangible form.
The liquefaction of some of these gases was a great
advance; but of late years immense improvement in
apparatus has rendered possible solidification of those
which for a time could be liquefied only.

Hydrogen has been the most resistant to treatment
of these older elements, and its liquefaction was rightly
regarded as a great feat; but Dewar, so well known
for his work in this line, has finally reduced the liquid
to the solid form.

From communications made to the French Academy
and the British Association the following particulars
are taken: The result was arrived at by utilizing the
extreme cold produced by the evaporation of liquid hy-
drogen itself—one portion of the liquid being made to
freeze the other, which action was long ago observed
in the rapid escape of liquid carbon dioxide. An insu-
lated beaker was partly filled with liquid hydrogen,
and closed with an adjustment containing orifices through
which the vessel could be emptied with great rapidity
by means of a pneumatic pump. The preparation for
the experiment was completed by immersing in the
liquid in the larger receptacle a similar vessel also con-
taining liquid hydrogen, cold to such a degree being
produced by the evaporation that the hydrogen in the
inner vessel was solidified. At first Professor Dewar
suspected that the solid thus obtained might be a re-
siduum of air adhering to the apparatus, or from air
and hydrogen combined in preparing the gas. By fur-
ther experiment, however, he became satisfied that the
product was really solid hydrogen.

The solid so obtained had the appearance of frozen
water—not of a metal, as might have been expected
from the markedly basic character of hydrogen. The
density of the solid was 0.086, and of the liquid at the
melting point 0.07.

The hydrogen for the experiment was obtained by
the action of pure sulphuric acid on pure zinc. The
temperature reached in the experiment was —265° C.,
the lowest degree yet attained.

It has been announced that Professor Dewar has
succeeded in liquefying helium by means of liquid hy-
drogen; and doubtless he will now endeavor to find a
way of reducing the newly discovered gas also to the
solid state.

Leucoplakia Buccal et Linguos.—An article on
this subject has been received at this office. The author
is requested to send us his name and address.

The First Lady Pharmacist in Paris.—Lyon medi-
cal for October 22d says that Mlle. Anna Fichtenholz,
a pharmaceutical graduate of the first class, who has
just opened a pharmacy at Passe, is the first lady phar-
macist established in Paris.

The Soldier's Pocket Dressing in South Africa.—Ac-
According to the Medical Review of Reviews for November,
every soldier's kit on active service has a field dressing
outfit sewed into a pocket on the inside of the jacket.
The outfit consists of gauze, gauze bandage, compressed
charpie, safety pins, and a piece of mackintosh. Directions
for use are printed on the inside and outside covers.

The Doctor's Ass.—Dr. Achilles Rose translates as
follows a story told in a recent number of Kappo:

In Egypt, physicians visiting their patients often
ride on asses. Asses are very popular in Egypt. Some
Asclepias dismounted at the door of a patient of his
who was suffering from pharyngeal abscesses. By ac-
Aid the physician entered into conversation with a friend. The
ass, finding the door open, entered the house and went
into a room on the ground floor, where the sick man,
in a state of fever, was lying. Taking the ass for the
doctor, he held out his wrist. The ass took the patient's
hand with his teeth. This frightened the sick man so
much that he gave a piercing cry. The abscess burst
and immediate relief followed. The doctor quickly
entered and looked for a stick to drive the ass out of
the room, but the patient said to him: "Do not strike
the ass, for he has cured me in two seconds, while you
have tyrannized over me for fifteen days."

The Society of the Alumni of St. Catharine's Hos-
pital.—About twenty-five physicians who in years gone
by were attached to the house staff of the hospital, in
order to keep up the pleasant memories associated with
their connection with that institution, have organized
the Society of the Alumni of St. Catharine's Hospital.
The officers elected are Dr. Maurice Enright, president;
Dr. George Wieseckel, vice-president; Dr. James S.
Slavin, secretary; Dr. William F. Linder, financial sec-
retary; and Dr. Michael J. Neville, treasurer.
The Propagation of Vaccine Virus.—The work of producing vaccine virus on a large scale has of late years come to be more and more recognized as an important adjunct to the practice of medicine. The widespread opposition to animal vaccine that had to be encountered twenty-five or thirty years ago was slowly overcome by individual investigators, but they were largely robbed of the legitimate reward for their labors by the appropriation of public funds to the business of producing vaccine for sale. The result has been that only concerns of large resources can now compete with the producers whose subsidies have enabled them to drive individuals almost entirely out of the field, and even those establishments can compete with the official only because they produce an article that is believed to be of superior quality. With them the business of propagating vaccine has grown to be so large that they are able to avail themselves of resources beyond the reach of others. These reflections have been called forth by the perusal of advance proofs of an illustrated article that is to appear in Therapeutic Notes. One of the illustrations we here present, the block having been kindly lent to us by Messrs. Parke, Davis & Co., whose establishment is described in the article. It shows a calf made ready to be turned on its back to undergo the necessary procedures. There is no particular novelty about the apparatus employed, but it is doubtless new to many of our readers. The lymph of former days, preserved in the form of a dry film on ivory or quill “points” or “slips,” has been to a great extent replaced by “glycerinated” liquid lymph. It remains to be seen if this change will prove to be of advantage.

A Portrait of Dr. John T. Metcalfe Given to the Academy of Medicine.—On November 18th Dr. T. Gail-lard Thomas wrote as follows to the president of the Academy of Medicine:

“I have in my possession a life-size portrait of Dr. John T. Metcalfe, of this city, which was painted for me by Lazarus, who a quarter of a century ago was famous as an artist. If the New York Academy of Medicine would honor me by accepting it as an addition to its gallery of eminent physicians, it will give me great pleasure to present it to them, and have it hung in the spot selected.”

The president replied as follows: “It affords me much pleasure personally to express in behalf of the council the gratification felt by your presentation to the academy of a portrait of our esteemed fellow, Dr. John T. Metcalfe. His long and eminent career as a physician has made him for many years one of the most distinguished representatives of the profession in New York, recognized as such not only in the medical world, but by the public as well, where his social position was second to none. It is eminently befitting the function of the New York Academy of Medicine to perpetuate by such memorials in its halls the men who have given tone and character to the medical profession of New York, and in no case could such a purpose be better fulfilled than by the reception of your most acceptable donation.”

The New York Hospital.—We learn that Dr. Francis II. Markoe has been appointed a visiting surgeon to the hospital.

The German Hospital Alumni Association held its third annual dinner at the Arion Club House on Wednesday, December 6th. Dr. Franz Torek presided, and the speakers were Dr. Abraham Jacobi, Dr. Hermann G. Klotz, and Dr. Henry J. Wolf.

The Physician as Beneficiary.—According to the Journal of the American Medical Association for November 25th, the mere fact that the beneficiary of a decedent was the testator’s medical adviser, the third appellate division of the supreme court of New York holds Taube Cornish’s Will, does not raise any presumption of undue influence, at least in a case where the beneficiary is not present at the transaction, and the will is drawn from instructions given by the testator himself.

The German Medical Society of the City of New York will hold a Stiftungssemmers this (Saturday) evening in Arion Hall.
ON THE PHYSIOLOGICAL CHARACTER OF THE PAIN OF PARTURITION.

By Samuel M. Brickner, A. M., M. D.,
Assistant Attending Gynecologist, Mount Sinai Hospital.
Out-Patient Department, New York.

Because the act of parturition, with very rare exceptions, is a painful one, some writers have been led to assert that the pain incident to childbirth partakes of a pathological character, or that it is at least pseudo-physiological in its nature. To admit the truth of this assertion is to admit the pathological nature of parturition itself, no less than to concede that evolutionary forces have been at fault. If the statement is made in good faith, it merits scientific inquiry, especially since in all available literature no other reference than the one given can be found on either side of the question.

It may be well at the outset to state that the discussion of the sensation pain, as it occurs in parturition, must not be allowed to include the injuries inflicted in a normal or an abnormal birth, nor the distress, the inconvenience, or the disadvantage of the attendant suffering. It is further necessary sharply to differentiate between the results of pain and mere states of being, since it is this fault which is responsible for the position taken by those who have inspired this study. Thus, they argue, the pain of parturition is distressing, inconvenient, and disadvantageous; it may be so severe as to give rise to permanent injury or to shock, or, occasionally, to a psychosis. The functions of the bladder and rectum are not painful and are equally necessary and important. Hence the pain of parturition is not in harmony with physiological laws.

In order that we may be absolutely accurate, let us define the terms "physiological" and "pathological." By the former is meant the execution of an act in a manner in harmony with the purposes of the acting organ—that is, in a natural manner. "Pathological" may be defined as the execution of a function in a diseased way, or in a manner which is not in harmony with the natural purposes of the organ.

A brief sketch of the accepted functions of the organs concerned in parturition will help further to elucidate and to emphasize their physiology. The uterus receives the impregnated ovule from the Fallopian tube, nourishes it through the peculiar organs developed during gestation, preserves it from harm and injury, and at the time when it is able to thrive alone, by its contraction and retraction, forces it into the

---

*Read before the Metropolitan Medical Society, September 26, 1899.
of the most interesting obstetric chapters. Since civiliza-
tion does not alone prescribe the limits of painless
or easy confinements, we must seek the cause of the
difficulty and pain of human labors in man's anatomical
structure. Here we find elements which are of a determin-
ing character. The upright posture of man, calling for a compact and well-knit pelvis, distinguishes
him from the quadrupeds. The perineum in man is
called upon to bear the weight of the viscera, and thus
offers great resistance to the parturient forces at the
time of labor. The pelvic canal is almost straight in
the lower mammals, while in man it is curved. In the
quadrapeds the head of the fœtus passes the sacrum
before it reaches the resistance of the pubic bones; and
when it is opposed by this bony structure, the freely
movable cauda is at the opposite pole to reduce the
resistance. If we add to these elements the movable
sacro-iliac joints, the frequent separation of the pubic
bones, the weakness and consequent easy stretching
of the perineum—because it is not obliged to support
the abdominal viscera—we have abundant anatomical
reason for the easier parturition of the lower mammals.
But even with these advantages, the quadrupeds, es-
specially those of a higher grade of development, are not
free from the pain of parturition, for evidence on this
head is overwhelming. If, indeed, the pain attending
parturition were confined to man alone, there might
be some justification in assuming that in the course
of his descent some factors had made him more suscep-
tible to pain than were his ancestors; or that his en-
durance of pain had become minimized. This we find
not to be the case. Other mammals offer to the con-
trary convincing data, and man appears to be able to
cure physical pain as well as lower animals. This
can be seen in the endurance of pain in soldiers and in
those whose susceptibilities have been lowered by their
manner of life. Martyrs at the stake seem to disregard
their physical pain in the ecstasy of patriotic or reli-
gious frenzy. The mental condition of the parturient
woman may be compared to that of the soldier on the
battlefield or to the martyr at the stake. The elation
and excitation incident to maternity, the love of off-
spring natural even to the most depraved, the innate,
uncontrollable desire to suffer for the good of the
species—these factors are important in helping her
endure the pain which is unavoidable. It has always
seemed to me, too, that women giving birth to illegiti-
mate children appear to suffer more actual pain in
childbirth than their married sisters, to whom the ad-
vent of a child is less of a disgrace if not always more
welcome.

It would be illogical, in the light of modern biologi-
cal work, to attribute temporary or permanent benefit
to physical pain; for all evidence goes to show that
organisms receive vital force—which may be translated
into benefits—from those things which are pleasurable,
while they are depressed by acts, necessary though they
may be, which are painful. They may, indeed, receive
permanent injury from the latter in so far as the sum
total of vital force is concerned. Yet we know that
in both the animal and the vegetable worlds reproduc-
tion is achieved only by the expenditure of energy, the
sacrifice of strength or nutrition, or both, on the part
of the parent forms. It will not be denied that the
female, in a biological sense, is designed mainly for
procreation. The mere fact, therefore, that in the act
of so doing she gives up energy in the form of pain
does not militate against the naturalness of partur-
tion, for she but conforms to the general law. Fur-
ther, we may assume that as each individual exists for
the benefit of the species—though not in the sense
of Schopenhauer—pain undergone for the benefit
of the species is not detrimental to or antagonistic
to the species. We see the most beautiful examples of
sacrifice for the species in some of the lower forms of
protozoan life, as in the gregarina, which reproduces
itself by resolution into a multitude of still more
minute masses, completely losing its identity as a
parent. Among some of the infusoria, similar phe-
omena of encystment, rupture of the envelope, escape
of numberless minute offspring, and, of course, com-
plete obliteration of the parent takes place. In these
instances, the death or complete annihilation of the
parent occurs for the sole purpose of reproduction.
Low as these forms are in the scale of life, the same
genetic principle applies to the higher forms; and we
may well assume that the pain experienced by mam-
mals in parturition is an exemplification of this prin-
ciple. And what is natural, first, and common to all
species, secondly, can not be pathological in the sense
in which we are accustomed to use the word.

Let us now regard this subject from another view
by taking a short survey into the causes of pain in the
act of parturition in the human female. We find that
the pain is due to two factors which are so integral a
part of the birth act as to be inseparable from it:
First, the stretching of the parts; second, the efforts
of the uterus against resistance. These two elements
are not distinctly separable during parturition, for the
uterus is working against resistance of the soft parts
at the same time that these are being dilated for the
passage of the fœtus. The first element in the genesis
of pain lies in the stretching of the cervix, and is due
to the dilatation and the tension of the cervical attach-
ments. This pain is referred by the parturient woman
to the lower lumbar and sacral regions, a fact in con-
sonance with clinical experience; for we find that pain
originating in the cervix, or caused by moderate or
severe irritation of that part of the uterus, is mainly
referred to these spinal regions. A little later, when
the uterine muscles begin to exert pronounced effects,
the uterine attachments are put upon the stretch as the
fetal head advances and encounters the resistance at
the pelvic brim. Each effort of expulsion is then ac-
companied by pain arising from the tension of these attachments. As labor still further advances, the vagina and the vulva must be stretched for the passage of the foetal head and shoulders. These are more sensitive than the other parts of the genital tract involved in the act of childbirth, and the pain toward the end of labor is, therefore, usually intense, amounting at times to keenest agony as the head passes over the perineum.

The pain evoked by the contractions of the uterus against the resistance of the soft parts which the foetus must traverse must next be considered. This pain may or may not be proportionate to the degree of resistance encountered. In primipare the resistance is usually greater than in women who have previously borne children, since the soft parts have not been stretched before. Multipare, however, who have weakened or atonic uterine muscles because they have been through the process of parturition, may suffer greatly; for, although the soft parts offer less resistance, the uterine muscles are not equal to the task before them.

We see, then, that the agonies of parturition are due to factors which are inseparable from the act of birth, and are to be traced to purely physical causes dependent upon the anatomical structures involved. Assuming that it is granted that the manner of giving birth is free from pathological features, it follows as a corollary that incidents inseparable from it must also be devoid of pathological significance. And it is important to recognize that injuries incidental to parturition, whether these take place in a normal or in an abnormal position or presentation, are separable and distinct from the pain proper and can not therefore be logically assigned as pathological causes of pain in labor. Temporary mental disturbances appearing post partum and shock have been attributed to the pain of parturition. Although it is likely that other factors were responsible for these pathological sequels, the contention may have a basis of truth. I will admit it, at least, for the sake of argument. But in the former case, mental aberration will usually be found dependent upon a vicious heredity, and shock may easily supervene in an otherwise uncomplicated case in an organism debilitated or especially susceptible to influences which in another body would be productive of no untoward symptom. However, the proper position to hold at the present time with regard to the unusual disturbances of pregnancy and the puerperium is, that these are not to be regarded as entities due solely to the functions of gestation and parturition, but as incidents thereof, these functions playing no aetiological role, or, at most, an inferior one.

As we have seen, the pain of childbirth is due to factors which have to do entirely with the birth canal. It is notorious, however, that it is no greater nor more difficult to bear when this canal is narrower than it should normally be, or when the child’s position is such as to render a birth more difficult than usual, although under these conditions the pain may be of longer duration because the act is longer in point of time. This delay, in fact, partakes of a physiological character, since it is due to the effort which is making for the adaptation of the child to the unusual or difficult passage furnished for its exit from the uterus.

The contention that of all the functions of the body which are important and necessary, parturition is the only one which is accompanied by pain and must therefore be non-physiological, is not, it seems to me, well grounded. The important functions of the bladder and rectum have been especially cited in the comparison of physiological functions as being free from pain. In the first instance, the vesical and rectal functions must be performed so frequently that severe pain—or, for that matter, any pain—in their execution would so work to the detriment of the organism that the continuance of life would be a great struggle. They are functions, further, which have to do with the vegetative life of the individual and have no bearing on the life of the species, as has the overwhelmingly important function of reproduction. Compared with the multiple performances of purely vegetative functions, that of genesis is an exceedingly rare occurrence. Moreover, the vesical and rectal pouches are easily opened under physiological conditions, there being no necessity for their remaining closed until the waste products they excrete attain a certain development, as we shall see is the case with the uterus and its foetus. It is no argument of strength, although it is an alluring one, to contend that because most bodily functions are painless, painful ones bear pathological stigmata.

A logical necessity for the tightly closed parturient canal, with its enforced dilatation at the time of birth, lies in the protection afforded thereby to the foetus during the entire period of gestation. Were it otherwise, the impregnated ovule would escape from the uterus soon after conception, or at once, and would perish. Among some of the lower forms of animal life in which uterine development is not possible or necessary, we find immediate escape of the ovule the rule. In sponges, polyps, and some of the coral animals the mature cells are simply ejected through the mouth opening from the intestinal cavity, or they pass out through the outer skin opening—as in the case of the hydra—or through an opening in the ventral wall specialized for the purpose. Indeed, this is the case in forms as high as worms, and even in a few of the vertebrated animals, as in the cyclostoma and a few of the fishes. But the impregnated ovule of the higher animals, including man, can not live outside of the body of the mother until a certain development has been reached. To secure to the foetus the necessary protection, the birth canal therefore remains closed until this development has been accomplished. This means increase of size and subsequent dilatation of the genital tract to secure
birth. Because this necessary stretching is combined
with pain by no means proves its pathological character;
for from the too brief sketch just given it is evident
that the dilatation is not only in harmony with natural
laws, but has a deep physiological significance, since it
is an inseparable accompaniment of a process which
from its inception is destined to produce a new individ-
ual in a manner at once safest, most protective, and
most economical; in other words, in a manner economi-
cal to the species and safe to the mother and the off-
spring.

The very character of the painful uterine contrac-
tions—one of the main sources of parturient pain—is so
beautifully adapted to the needs of mother and child
that their physiological nature is self-evident. Were it
not for the intermittent nature of these contractions the
parturient woman would be unable to endure the tre-

cendous muscular strain called for, and would become
exhausted before the birth of her child. The fetus, too,
would perish in its birth from the cessation of the pla-
ceental circulation due to the constriction by uterine
muscle fibre. Pathologically, indeed, we find this ac-
tually to be the case.

It is granted among students of biology and ethics
that physical pain is a stimulant to action. A common
example may be cited in the fact that when we wish a
horse to exert himself we whip him. Exhausted dry
bullocks in India and Abyssinia are horribly tortured to
cause them to renewed effort. So in the female, the
pain evoked during the second stage of labor is an in-
centive to further effort to get rid of her young. The
action of the abdominal muscles, which play a very
important part in the expulsive forces of the second
stage, is a voluntary one. Under the stimulus of the
expulsive efforts they act automatically, but can still
be held under the control of the patient. Even in the
agony of the final pains, the woman, by opening her glot-
tis and screaming, can suspend the action of these mus-
cles. This has well been called by Tyler Smith the
safety-valve action of the glottis. But women do not,
as a rule, attempt to control these muscles. They
“bear down,” as it is called, and follow the instinct to
do so naturally. The expulsion of the fetus is facili-
tated by this tremendous vis a tergo, which still remains
voluntary, although it is automatic. We may attribute
the action of the abdominal muscles to two causes: 1.
To the natural, therefore physiological, efforts at ex-
pulsion. 2. To the stimulant effect of the pain induc-
ing a voluntary, though at times automatic, added effort
to get rid of the pain-producing element, even though
greater pain is caused by the muscular action. We
might add as a corollary to this that those women who
have inefficient pains—that is, poor contractions of the
uterus or the abdominal muscles—have less pain than
those whose contractions are vigorous, and their labors
become pathological and end usually by artificial as-

There is still another reason, partly physiological,
partly biological, for assuming that the pain of parturi-
ton is of a truly physiological nature. This is the lack
of the revivability of the memory of the pain. The
pain of other agonies is, as a rule, keenly remembered;
but it is notorious that women forget the pain of par-
turition within a few days or weeks of its occurrence.
This is in accordance with the views we have taken of
the pain, for from the biological standpoint it is impor-
tant that the pain should be forgotten, or at least
its agony, lest its presence in the memory be a deterrent
from further efforts at procreation. This inability to
recall the pain of parturition is, as well, a proof of its
physiological character, as it is equally well known that
pain of a pathological nature, or one evoked by a path-
ological process, is subsequently easy of description and
is not lost in the memory.

To consider in detail the steps by which the mamb-
mal has reached his present mode of reproduction
would lead us too far afield. We have seen, discussing
the necessity for a closed parturient canal in the mamb-
mal, that almost all conceivable methods for the expul-
sion of the mature fetus exist among animals. Inter-
esting as the subject is, we can not now consider the
multiple varieties of reproduction, beginning with sim-
ple fission and ending with the birth of a human being.
But in the course of the evolution of these processes—
from simple fission to budding, then the budding of a
particular part, next the placing of the budding organ
in an interior cavity for greater safety, then increasing
complexity of the reproductive organ, finally sexual re-
production, with its wonderfully manifold variations—
in the course of the evolution of these processes, I re-
peat, the mode of inclusion in an internal uterus, as we
know it in the human female, was evolved as a true
variation. It may be objected to with some show of
truth that, if the variation is a true one, its function
should not be accompanied by pain. But Darwin him-
self, in the discussion of the laws of variation, states
the significance of correlation. And he has shown con-
clusively, I think, that many modifications are of no
direct service to the individual, having arisen in correla-
tion with other useful changes. Expressed in the terms
of our discussion, this means that the pain which is
incident to labor stands in direct relation to the manner
of birth, the method of birth, again, being a useful
modification or change—useful to the species, since its
continuance is subserved; useful to the new being, since
its safety has been conserved.

I regret that I can not go more deeply into this sub-
ject on the present occasion, for I have but scratched
the soil. I hope, however, that I have added argu-
ments sufficiently lucid and strong to prove that our
conception that the mode of reproduction in mammals
is physiological is correct and scientific. Briefly sum-
marized, these are my conceptions in behalf of this
view.
1. What is natural can not be pathological. The functions of the uterus are natural and include the reception of the impregnated ovule, its nourishment and retention until development is complete, and then its expulsion.

2. During the intra-uterine life of the fetus the parturient canal remains closed for the protection of the fetus. Its dilatation at the time of labor is painful because sensitive parts are stretched. The pain is therefore inseparable from parturition. Parturition being natural, it follows that inseparable incidents are also natural.

3. This pain is common to all animals which give birth to their young from a uterus with a placental attachment.

4. Compared with other important functions, parturition is a great rarity. If the commonly repeated functions were painful, the species could not continue its existence. There would be no gain in having the vegetative functions painful. The one is in the life of the individual, the other in the life of the species.

5. The uterine contractions are chief among the causes of the pain. Their intermittent character, which provides safety for mother and fetus, proves their physiological nature.

6. The pain of parturition in the second stage is a stimulant to renewed effort for the expulsion of the fetus.

7. The lack of revivability of this pain in the memory soon after its occurrence, while pain of another character is easily remembered, proves its biological importance.

OBSERVATIONS UPON
FLAGELLATED MALARIAL PLASMODIA.*

DESCRIPTION OF TWO VARIETIES.

By CHARLES F. CRAIG, M.D.,
ACTING ASSISTANT SURGEON, U. S. ARMY;
PATHOLOGIST AT THE CAMP COLUMBIA HOSPITAL, HAVANA, CUBA;
FORMERLY PATHOLOGIST TO THE STEINBERG U. S. GENERAL HOSPITAL,
CHICAGO, ILL., AND THE JOHARI SIMPSON U. S. GENERAL HOSPITAL, FORTRESS MONROE, VA.

Ever since the discovery of the plasmodium of malaria by Laveran the nature and significance of the flagellated organism have constituted a mooted question. Held by some authorities to be of a degenerative nature, and by others as evidences of vital activity, the flagella have been closely studied, and a considerable literature has been accumulated concerning them. In the light of recent research, it can no longer be doubted that the evolution of the flagellated organism is a vital and most important phase in the life history of the plasmodium, and that the theory that it is a degenerative body must be abandoned.

During the past seven months I have had the opportunity of studying the blood of a large number of soldiers returning from Cuba and suffering from tertian and astivo-autumnal malarial fevers, and one of the points of greatest interest has been the study of flagellated organisms. As the result of these studies I believe that there occur in the blood of cases of tertian, and especially in the blood of cases of astivo-autumnal fever, two forms, or perhaps varieties, of the flagellated organism. Before describing them, a few words regarding the best way of obtaining flagellated organisms may be of interest.

Method of Obtaining Flagellated Organisms.—It is a well-known fact that under ordinary circumstances flagellated plasmodia do not appear in a specimen of blood until some time after it has been removed from the body, generally from fifteen to twenty minutes. This rule has exceptions, however, for I have seen flagellated organisms in a blood specimen which had only been removed two minutes from the circulation; this is a rare exception, and even in specimens long removed from the body flagellated bodies are not always found. I have found the following method of obtaining these bodies at once simple and effective. The finger or ear is carefully cleansed with alcohol, as are also the slides and cover glasses. A small elastic band is now placed around the finger, or, if the lobe of the ear is used, it is compressed by an assistant. The puncture is made with a sterile needle or lancet and the first drop of blood wiped away. A second drop is now squeezed out and allowed to remain exposed to the air until the slide is breathed gently upon by the operator, when the tip of the drop of blood is gently pressed upon the surface of the slide which has been breathed upon. The cover glass is then immediately placed over it, and the prepa-
ration is ready to examine. The slight exposure to
air, and the small amount of moisture upon the slide
caused by breathing upon it, seem to hasten exflagella-
tion, for specimens so prepared almost invariably con-
tain flagellated bodies. In specimens prepared in this
way I have seen as many as twenty flagellated bodies in
one preparation, and have often observed two in a sin-
gle field. In my observations upon the bodies in ques-
tion I have used this method exclusively, and have never
experienced any difficulty whatever in finding material
—i.e., flagellated bodies—for study.

Description of Flagellated Forms.—As has been
stated in the early part of this paper, in many cases of
tertian malarial fever, and almost invariably in cases
of aestivo-autumnal fever, I have observed two seem-
ingly distinct forms of the flagellated bodies. By this
statement it is not meant that every case of tertian or
aestivo-autumnal fever examined showed these forms,
but that the cases showing flagellated bodies presented
them. While the two forms were often noted in tert-
ian fever, they were by far the most common in aestiv-
autumnal fever, and, as flagellation is generally con-
ceded to be of vital importance in the life history of the
parasite, this fact agrees with the well-known tenacity of
the aestivo-autumnal infection. These two forms of
flagellated parasites I have ventured to designate re-
spectively as the active and passive flagellated plasmo-
dium.

Description of the Active Flagellated Plasmodium
(Tertian Fever).—In examining a specimen of blood

![Fig. 1](image_url)

from tertian fever a number, sometimes only one or two,
of large, almost circular, bodies are noted, with the char-
acteristic pigment distributed over the surface, and in
very active motion. The motion is aptly described as
dancing, and is very much more rapid than that ordi-
narily present in the parasite, and at once attracts at-
tention for that reason. Quite often, however, these
swollen bodies will be seen, the pigment when first no-
ticed being immotile, but suddenly developing very ac-
tive motility while being observed. When the pigment
is immotile it seems to be collected in small blotches or
spots within the protoplasm of the parasite, but when
in motion it is distributed quite evenly throughout the
protoplasm (see Fig. 1, A and B). Besides the very ac-
tive motion of the pigment granules, if the edge of the
parasite is carefully watched, it will be seen that it also
is in motion, undulating and protruding, as though, as
Richard said, something contained within the para-
site were trying to escape. In a variable length of
time—from five minutes to half an hour or more—the
pigment will be seen to collect more centrally, the
motility being somewhat lessened, and instantly, like an
explosion, there appear at certain portions of the edge
of the parasite long, thin, colorless, actively moving
filaments, which undulate rapidly, lashing about among
the red corpuscles, to which they impart sometimes a
peculiar spinning motion. The filaments may number
from one to five, and are usually long and thin, having a
slightly clubbed extremity (see Fig. 2). The junction
of the flagellum with the parasite is not visible, it seem-
ing to be continuous with the periphery of the or-
ganism.

Besides the clubbed extremity, the flagella some-
times show small nodular swellings in their course, and
also a few grains of pigment, which may be distributed
along them or collected at the extremity (Fig. 3). They
generally measure about two or three times the di-
dermeter of the parasite from which they spring, but
sometimes may be even longer. There also occur
shorter, stouter forms, having a more sluggish, serpen-
tine motion (Fig. 3).

There may now occur one of several things: either
the flagella may break loose from the parent parasite,
among the blood-corpuscles for a variable length of time, seemingly trying to free itself from the mother parasite, it at last succeeds, and swims off in a serpentine manner among the red corpuscles (Fig. 4). In some cases the flagellum tugs very vigorously in its efforts to free itself, actually pulling the mother parasite about, but, of course, for only a minuto distance. After it has become free it may exhibit motion for a long time, even an hour or more. If it chances that the flagellum was the only one given off from the mother parasite, the pigment of the latter becomes motionless, the parasite quickly shrinks, and soon only a mass of pigment and degenerated material remains (Fig. 4).

In the second case, after persisting for some time, from half an hour to an hour or more, the flagella gradually become motionless and disappear, while the pigment ceases moving and the body of the parasite shrinks, becomes vacuolated, and soon presents a mere clump of débris.

In the third case, after a certain time, the flagella become less actively motile and seem to become entangled with the body of the parasite, thus seeming to be folded about it, sometimes loops being formed by the attachment of a flagellum to the mother parasite. The pigment in the body of the parasite becomes motionless and the same degenerative changes occur as in the former case (Fig. 5).

In the last case the parent parasite, either after the escape of one or more flagella or, in cases where no escape takes place, breaks up into two or more parts, each part containing pigment, which remains in active motion for some time. On careful observation it will be seen that the fragments are united by very delicate hyaline threads. The flagella soon lose their motility and disappear, but the fragments containing the pigment may persist for a long while. In one case the pigment was seen to be in active motion in one of the fragments of such a parasite after a period of eight hours, at a room temperature of 70° F.

In Fig. 6 is sketched the process of fragmentation as observed in a flagellated organism.

The form of flagellated organism just described is the most common form found in the blood of tertian malarial fever. The same form is also found in estivo-autumnal fever, but varies somewhat in morphology, but in unessential particulars.

In estivo-autumnal malarial fever the active flagellated form of the malarial parasite is smaller in size than is the same form in tertian malaria, is more oval in outline, as a rule, and the pigment is somewhat more coarse, and sometimes arranged in a wreathlike form. These differences are illustrated in Fig. 7. The same phenomena are observed here as in the case of the tertian flagellated organism, and which have just been described.

The chief facts to be noticed in our study of the form of flagellated malarial parasite which we have chosen to call the active form are: the extreme activity of the pigment in the parasite prior to exflagellation and during the time the flagella remain attached to it; the clubbed extremity of the flagella, and the separation and consequent individual existence of the flagella, and their power of individual and progressive movement in the blood.
Description of the Passive Flagellated Plasmodium (Estivo-autumnal Fever).—The form about to be described occurs also in tertian malarial fever, but in much smaller numbers than in estivo-autumnal fever, so that I have chosen to describe it as it occurs in the latter form of fever, the only difference being that it is larger in the tertian fever. Before describing it, however, it should be understood that not every case of estivo-autumnal fever shows flagellated organisms. They will only be found in the peripheral blood in those cases of fever showing crescents, for it is from the crescent that they develop. It is not often that one has the good fortune to witness the development of the crescent into a flagellated organism, and the following observation is therefore of importance. In observing a sample of blood from a case of estivo-autumnal fever which was particularly rich in crescents, I observed a medium-sized crescent entirely inclosed within a red corpuscle, occupying about one half of it. While under observation the crescent suddenly seemed to expand into a round body, the pigment, motionless, occupying the centre. After about ten minutes this round body suddenly became free, the red corpuscle seeming to melt away from around it, remaining as a pale shell close to the now free round body. Within a short time, probably about five minutes, the pigment within the round body became motile, at first slowly, then very rapidly, distributed throughout the protoplasm of the organism, and suddenly two flagella shot forth from opposite sides of the parasite. One of these afterward became detached and was lost sight of; the other, after persisting for about half an hour, ceased moving, and it and the body of the parasite became shrunken and degenerated.

This observation conclusively proves two things: First, that the crescents are developed within the red blood-corpuscles, and second, that the active flagellated parasite is developed from the crescents (see Fig. 8). It will be noticed that in the above observation it was the active flagellated parasite which was developed, and not the passive form, which will now be described.

The Passive Flagellated Parasite (Estivo-autumnal).—I have chosen to describe this form as it occurs in estivo-autumnal fever, because it is most numerous and most characteristic in the blood of such cases.

In the blood of those cases of estivo-autumnal fever containing crescents will be noticed numerous round and oval bodies in which the pigment is arranged in a wreath-like form. These bodies seem to be of two kinds. First and most numerous are those in which the pigment is of rather dotlike or rodlike form, and fine, sometimes motile and sometimes not, and those, fewer in number, and almost always round, in which the pigment is arranged in large black or dark-brown dots, in a perfect circle, and almost never motile. From the first variety arise quite often the active flagellated organism, which has already been described; from the last, the passive flagellated organism. These two forms are illustrated in Fig. 9.

The last-named round bodies merit a more minute description. They are clear cut and definite, perfectly circular, and appear to possess a somewhat granular protoplasm; the pigment is arranged in round, very dark dots, forming a perfect circle, which may, however, be arranged to one or the other side of the protoplasm of the organism. The pigment is generally non-motile, but occasionally a peculiar trembling motion may be observed; but the pigment retains its circular arrangement always, unless degenerative changes occur (see Fig. 10).

No matter how long such a round form is watched, it will never be seen to present the phenomena of exflagellation. The pigment does not become active and distributed throughout the protoplasm, nor do flagella emerge from within it. But in examining blood containing these bodies some of them are seen to possess one, two, or more flagella. These flagella are somewhat peculiar. They seldom possess a clubbed outer extremity, as in the case of the active flagellated body, but at their juncture with the round body a node is often noted which resembles exactly the clubbed extremity of the flagellum of the active flagellated body. The movements, also, of these flagella are peculiar. Instead of the rapid serpentine lashings seen in the flagella as put forth from the active parasite, the move-
ments were of a different character. The flagella seem to straighten and then relax, revolving apparently very rapidly upon their axes; sometimes they may be seen to pull themselves loose from the round body and again become attached to it. In the meanwhile the pigment within the round parasite has maintained its circular form, and is, at most, very slowly motile (see Fig. 11).

![Fig. 11.—Passive flagellation as observed in estivo-autumnal malarial parasite. In these figures note circular arrangement of pigment, the flagella without clubbed ends, and straight outlines. In one figure a flagellum is seen just before attachment to the round body.](image)

Sometimes no nodular swelling is noted at the point of attachment of the flagella, and in such parasites the pigment has a more rapid vibratory motion.

This same form occurs in tertian fever, but is larger, the pigment is less regularly arranged, and it is very much more rare.

The question arises, What do these forms of the malarial parasite signify? A few months ago, in a conversation with Dr. Thayer, he mentioned the occurrence of these peculiar flagellated bodies, and thus called my attention forcibly to the fact of their occurrence, which I had noted but had not paid much attention to. Since that time I have convinced myself that these forms occur, not as a rarity, but very often, and that they represent, as has been suggested by McCallum, the efforts of flagella, which have been set free in the circulation, to penetrate into the interior of a parasite, represented by the round bodies just described. While I have not been so fortunate as have McCallum, Thayer, and others as to have actually seen the disappearance of a flagellum within one of these parasites, I am convinced that this does occur from what I consider sufficient evidence to prove the fact. From the appearance and character of the motion of the flagella, and the passive condition of the organism to which they are attached, it seems to be impossible to believe other than that these flagella are striving to push their way into the parasite, and the fact that flagella have been seen to become detached from the parasite and again attach themselves to it, is almost conclusive proof that such is the fact.

The circle of events is, then, I believe, as follows:

The active flagellated organism is developed from the full-grown tertian organism and the crescentic estivo-autumnal organism. Flagella are produced and liberated, the mother organism, her duty fulfilled, degenerating and perishing. The free flagella swim actively about among the blood-corpuscles until they come in contact with the peculiar round, passive parasite, which they endeavor to penetrate. McCallum and Thayer have seen this penetration occur, one of the flagella becoming submerged, so to speak, within the substance of the parasite.

The nature of the process we are as yet ignorant of, but these two varieties of flagellated parasites do occur in the blood in malarial fever, and the observations upon them so far conclusively prove that the flagellate-body is not a degenerative body, but is, without doubt, a very highly developed vital form of the plasmodium of malaria. It is but reasonable to suppose that these forms are calculated to preserve the life of the parasite outside of the human economy, as they arise only when the blood has been exposed to external conditions, and that we have in this process another proof of the extracorporeal existence, in another form, of the malarial parasite.

My thanks are due Dr. Thayer for his suggestions regarding the forms described, and which prompted this research.

Note.—Since the writing of this article I have had the opportunity of confirming the observations noted at the United States General Hospital, Presidio of San Francisco, in cases of malarial fever in soldiers returning from the Philippine Islands. To Colonel A. C. Girard, commanding officer of that hospital, and to Major Charles Richard, late commanding officer of the Simpson General Hospital, my thanks are due for their kindly interest shown and the facilities offered for the study of the subject.

A REPORT OF THE OPERATIVE TREATMENT OF SEVERAL CASES OF FRONTAL AND MAXILLARY SINUSITIS.*

By FRANK WHITEHILL HINKEL, A.M., M.D.,
Professor of Laryngology in the Medical Department of the University of Buffalo.

The operative treatment of chronic purulent inflammation of the frontal sinuses has still enough freshness of interest to warrant a report of the details of a case upon which I have operated successfully. Briefly stated, the history is as follows:

Mr. B., aged thirty-eight years, was attacked by epidemic influenza in February, 1898, with severe pain over the left eye, followed by free purulent left-sided nasal discharge, at times of an offensive odor. For a number of years he had been subject to hay-fever symptoms in the summer time, with occasionally wheezy breathing, especially if in the country. When first ex-

* Read before the American Laryngological Association at its twenty-first annual congress.
Hinkel: Frontal and Maxillary sinusitis

In September, 1898, there was free offensive purulent discharge from the left nostril. There were left supraorbital pains and tenderness at times of the left eyeball. The general health was somewhat impaired.

Examination showed some crusts and muco-pus beneath the left middle turbinate. There was slight tenderness on pressure over the left antrum and left frontal sinus. Antral translumination showed relative darkness of the left malar region. An imbedded root of the left superior second bicuspid was extracted and found sound and not penetrating the antral floor. The floor of the antrum was broken through and the alveolar opening enlarged, after which a large amount of very offensive pus was syranged from the antrum. This treatment was kept up for a month by the patient at his home at a distance from Buffalo. There was then a very little flocculent discharge from the antrum without offensive odor, but pus continued to drain from the extreme anterior portion of the left middle turbinate immediately after the antrum was syranged clear. The anterior extremity of the left middle turbinate was then removed. In another month the patient reported with an increase of discharge from the left nasal chamber, and occasional left supraorbital pain, followed usually by increased nasal discharge. There was slight tenderness on firm pressure over the left frontal sinus. Frontal translumination was excellent on the right side and revealed a large sinus. There was darkness over the left supraorbital region. The left antrum contained a large amount of pus and presented the usual signs of antral empyema.

Opening of the frontal sinus was now recommended. In January, 1899, the patient, who had lost weight and whose general health was beginning to fail, consented to the operation. On January 23rd, at the Buffalo General Hospital, after shaving the left eyebrow, an incision was made along the inner half of the left supraorbital ridge to a little beyond the middle of the glabella, the soft parts and periosteum were retracted, and the anterior wall of the left frontal sinus opened with a small trephine. The sinus was found filled with a greenish, offensive pus. The incised tissues were protected by a dam of iodoform gauze and the sinus flushed with normal salt solution. There was no immediate wound healing up. The sinus was large, extending far over the left orbit. Its walls were thoroughly curretted and the nasofrontal canal, located by a curved probe, was enlarged with a trocar and curette until an ample opening communicated with the nasal chamber, presumably through the anterior ethmoidal cells. A strip of iodoform gauze was introduced into the nasal chamber through the enlarged infundibulum, as suggested by Birvan, and the external incision closed by silk sutures. A dressing of gauze and cotton was applied and retained by bandages. Intranasal insufflations of iodoform were made every three hours, after gentle spraying of the nose with normal salt solution. No other treatment was given. There was no rise of temperature. The gauze drain was removed on the third day. On January 30th, the sixth day, the wound was redressed and the stitches were removed. There was good union. On February 1st, the eighth day, the patient was discharged from the hospital. The left antrum on syringing was found entirely clear and no subsequent unusual discharge occurred from the left nasal chamber. There has been no return of symptoms of disease.

The points of interest in this ease history are the masking of the primary frontal empyema by the symptoms and signs of the secondary antral abscess; the persistence of the antral discharge despite drainage and cleansing of the antrum, and its immediate cessation as soon as drainage of the frontal sinus was secured. I dressed the wound after suturing with cotton pad and bandage in preference to any form of colloidon dressing. It seems to me that the difficulty of securing good union after evacuating so infected a cavity is increased by any dressing that confines the exudate about the wound and prevents evaporation. As there were no indications for intranasal interference after the operation, no syringing of the frontal sinus was employed. Thorough drainage having been secured, the parts were left to Nature, the nose alone being gently sprayed and its mucous membrane kept under the influence of iodoform.

I wish to report three operations for chronic antral empyema in which I followed the method of Luc, with the details of which I was first made acquainted through a communication of Dr. de Roaldes. Each of these cases was of great chronicity, and one presented a double empyema. As I wish to present for discussion only the operation histories, I give the case histories but briefly. In each case I followed the usual steps for laying bare and opening the anterior wall of the antrum, and I will confine the descriptions to the novel features of the operation—the opening of the nasal wall of the antrum beneath the inferior turbinate and the immediate closure of the gingivo-labial incision. I found the haemorrhage following the incision into the gingivo-labial conjunctiva lessened by an injection of a one-per cent. solution of cocaine hydrochloride beneath the mucous membrane just as the anaesthetic was about to be administered. In one case, in which I had been treating the antrum through Freeman’s cannula beneath the inferior turbinate, I was able to reduce the haemorrhage, that is so profuse when the antrum is opened, by injecting into the antrum just before the operation about a drachm of a solution of suprarenal capsule.

Case I.—Miss S., aged thirty-seven years, empyema of left antrum, marked by moderate discharge and at intervals deep-seated pain in the malar region. On February 9, 1899, at the Buffalo General Hospital, with trephine and bone forceps I removed part of the anterior wall of the left antrum. There was no particular difficulty in breaking down the nasal wall beneath the inferior turbinate. I passed a curved trocar within the nostril and beneath the anterior extremity of the inferior turbinate and readily broke down the thin antral wall. Using the point of the trocar as a guide through the freely welling blood within the antrum, I enlarged the opening freely with a sharp spoon. I encountered great difficulty in endeavoring to pass an iodoform-gauze drain from the antrum through the nasal chamber and out at the nostril. I closed the gingivo-labial incision with silk sutures. The escape of air through this aperture for several days when the

* Considerations of the Radical Cure of Chronic Empyema of the Antrum of Highmore. New Orleans Medical and Surgical Journal, December, 1899.
nose was blown showed that the closure was imperfect. However, by the fifth day, when the stitches were removed, the incision was closed. A small area of numbness about the left angle of the mouth was noticed for several days after the operation. After the fifth day the antrum was flushed by means of a Eustachian catheter through the opening in the nasal wall. A slight amount of muco-pus escaped at each washing. After several weeks the nasal opening contracted so that a small cannula could not be introduced and there was some return of pain. Under cocaine I cut away the anterior dependent portion of the inferior tubinatated bone and with a sharp spoon enlarged the opening into the nasal wall of the antrum. This procedure was followed by relief, and on April 27th the patient was discharged apparently well.

Case II.—Mr. B., aged twenty-one years; double antral empyema, with chronic cough, expectoration, and naso-pharyngeal hypersecretion. At the hospital, on February 13, 1899, I opened the anterior walls of both antra. The hemorrhage was very free; the anterior antral walls presented an unusually small area for operation, and they were unusually thick. In consequence I was not able to secure entirely satisfactory access to either antrum. I was unable to pass gauze or drainage tube through the perforation in the nasal wall, and, as the hemorrhage was very free and the patient’s condition not first rate, I did not carry the operation beyond as thorough a curettage of the antral walls as was possible. I persevered in the original plan of the operation, however, closing one side with stitches and allowing the other to fall into place without stitches. The unstitched side healed apparently as firmly and as speedily as the other. A large area of numbness on the right side followed the operation, extending from the lower margin of the orbit to the upper lip as far as the median line and somewhat over the labial mucous membrane. This gradually disappeared. The patient was compelled by business engagements to go to his home in a neighboring town soon after the operation, and I was able to see him only at rather long intervals. The nasal openings rapidly contracted so that I was unable to flush the antra satisfactorily through the nose. Had drainage tubes been introduced the patient could probably have irrigated his antra himself. The result of the operation has not been satisfactory and I await an opportunity to repeat it.

Case III.—Miss M.; left antral empyema, operated on at the Buffalo General Hospital, on March 9, 1899. The inferior turbinant was dependent and lay close to the antral wall. I removed the anterior portion of it to facilitate the passage of the trocar into the antrum. I did not introduce a drainage tube into the nose. After a counter opening had been made beneath the inferior turbinate the gingivo-labial incision was allowed to fall into place without stitches and union followed nicely in a few days. However, a small abscess occurred later on the margin of the wound requiring curettage. It did not communicate with the antrum. This case improved rapidly for several weeks. The antrum was readily flushed through the nasal opening, and I found injections of alcohol serviceable in reducing the discharge and lessening its purulent character. In about three weeks the nasal opening began to grow small and the discharge to be somewhat confined within the antrum. On April 19th I enlarged the nasal opening under cocaine with a curette, and have used since at intervals injections of alcohol and of a solution of iodoform in ether. Since May 26th there has been no unusual nasal discharge nor any symptoms of antral disease. Antral transillumination is equally good, though there is no left pupil glow. This case, therefore, may be considered cured.

Valid conclusions as to the value of this operation can not be drawn from so limited a number of cases, but I offer their details for your consideration and discussion. The limitations of the operation and the proper choice of cases for its performance will be facilitated by reports of its results, whether successful or otherwise. I see several directions in which my own technique can be improved in subsequent operations. The introduction of the drainage tube I have found the most difficult step in the operation. To facilitate this, I have had made for me a modification on a small scale of Belloq’s cannula. Introduced through the nose and with the probe point thrust forward and upward into the antrum, it brings readily into reach the ligature to which the drainage tube or strip of gauze can be attached and then drawn through the opening in the nasal wall and out at the nostril.

The suturing of the gingivo-labial incision seems from my limited experience to be unnecessary. It is difficult to keep the stitches already inserted from being somewhat torn out during the later stitches on account of the manner in which the parts must be drawn upon to secure access to the lips of the wound.

The parts coapt readily without stitches and there is but little necessary motion of the gingivo-labial fold. The wound need not be disturbed if the patient is fed upon soft food, taking care in eating to use the side of the mouth opposite to the operation and to avoid blowing the nose violently. As shown by my second and third cases, healing occurs readily without stitches if a little care is used.

A WOMAN’S VIEW OF CHICKAMAUGA.*

By HELEN W. BISSELL, M. D.,
ST. PAUL, MINN.

The country was very beautiful on the July day when, in company with a graduate from Grace Hospital, Detroit, I passed through the Tennessee mountains on my way to Leiter Hospital. There were frequent showers during the afternoon, but instead of cooling the atmosphere they added a murkiness to it which rendered it almost unendurable. After our late dinner in Chattanooga we started on our way to Lytle, to take from there a carriage to Chickamauga, where we found that only the considerable rank of the officers who accompanied us made it possible for us to pass through the many lines of pickets thrown around the camp.

Leiter Hospital was a handsome hotel a few years

* Read before the Minnesota State Medical Society, June 21, 1899.
ago, broad of front, with wings running back from each end forming an open court, behind which stood Ward A, the old-time dancing hall, making a comfortable place for forty patients.

What was our astonishment on going up the steps to find a double row of beds filled with men! Some of them stirred and slightly rose as we came to the veranda, but the greater part lay quiet in their first sleep. There were about fifty of these soldiers, convalescents, who had been transferred from the wards in order to make room for acute cases.

The nurses’ rooms, which were in the third story, were so crowded that at first we were obliged to take beds used by the night nurses. So cheerfully, however, were we invited to do so by the right-fal owners that we felt at once we were in a place where, whatever might be its trials and inconveniences, there existed an unusual degree of hearty good will. This became more apparent as time went on, and it had its sources, first, in the patriotism of those engaged in the work, and, secondly, the high courtesy of the major-surgeon, Dr. E. C. Carter, of the regular army, a Virginia gentleman, who cared for and directed all.

A long-unused and hastily arranged building can not be made a perfect hospital, and the first view, to one accustomed only to the finished institutions of our large cities, was far from encouraging. As rapidly as possible suitable plumbing was put in the building, but for some time the work was greatly hampered by the structural defects of the building.

So rapidly were the first patients rushed into the embryo institution that it was necessary to take the place most nearly empty, which happened to be the billiard room in the basement. It was always damp, but the crowding was so great that it was simply a choice of leaving men on the ground in the camp, or putting some of them there. So far as I could learn, there were no evil effects from the location.

Army rations taken out of doors under tent flies, in all weathers, with cats, dogs, pigs, and chickens in daily attendance, with an occasional cow or mule to add an element of variety to the scene, was not ideal. But we petted the cats and threw crumbs to the chickens, so that when a fence was put around the grounds we really missed the rusticity of that part of our life.

Salt pork, beans, good bread without butter, and fair coffee, with a scant supply of milk, can not be considered desirable when the temperature is high above a hundred and one is worn from the humid atmosphere and necessary overwork. Oatmeal becomes infested with insects so rapidly that it can not be considered reliable in such a climate. After a time sufficient money came into the major’s hands to allow of some additions to the regular fare, and during the latter part of our time we had little to complain of in that particular.

The convalescents, who ate at the same table and of some of the same articles, occasionally found fault, but the food supply for the really sick was above criticism. Milk, eggs, soups, toast, etc., in abundance, with the addition of ice, jellies, and canned fruits, provided by the various Red Cross and Daughters of American Revolution societies, made as full a variety as could easily be found in our best-equipped institutions.

I wish to state emphatically that I never knew supplies to be misappropriated. Great complaint was made about the non-reception of two boxes sent to the soldiers from our home society, so I looked up the matter, and criticism was stopped when one was found to have contained abdominal bandages instead of eatables, and another, filled with gauze dressings and plaster bandages, was regarded with disgust.

I was sent into one of the wings where there were large rooms for four and smaller ones for two patients, though it was necessary at times to put five in the larger and three in the smaller apartments.

On account of the extreme heat, most of the transfers from the camp hospitals were made at night, and as I was on duty at that time I had an unusual amount to do in the reception of patients. Most of them were from the Second Division and regimental hospitals. I could hardly credit my senses, many of the men were so dirty and neglected, and at times I was glad that a patient’s temperature was found to be so high that he could be put into a bath for twenty minutes, for then between the soaking and the necessary friction he would become tolerably clean. Hardly one came in who did not require a full bath, and it frequently took three days to make the patient satisfactorily clean, for severe typhoid does not allow of as much moving and changing as one might desire.

Almost without exception the roughest soldiers became gentle and manageable, seeming like tired boys who had got home, and their efforts to use respectful terms and delicate language were pathetic through verbal mistakes. They were generally truthful, and I never heard more serious deviations from accuracy than the pardonable departures made by convalescents from typhoid fever as to the exact quantity of food that had been ordered by the doctors for their meals. They never complained of or regretted their illness; only felt it hard that it had come upon them while idle instead of during actual warfare. As a rule they were young, the greater portion being under age, and some of eighteen seemed more like homesick boys than martial men.

My work was principally among northwestern and southern men, and when I saw the powerful Dakota and Montana soldiers lying beside those equally strong and determined from Arkansas and Mississippi, I understood why the battles of the civil war were so terrible, and how with their strength combined our nation becomes invincible.

I was so distressed at the state of a Western sol-
dier who was brought in dying that I went to his camp to find out the reason of his condition. I think that without exception he was the most splendid specimen of young manhood I had ever seen, and, while well nourished, his labored breathing showed meningitis had begun its work.

It was the day before the grand parade that I went with one of his comrades, carrying with me some supplies and money from my home Red Cross society. I saw first the captain who had command of my escort's company. When he found I had melted milk he asked for it at once for one of his soldiers who was on the ground, and for whom there was no place in the hospital. It was almost impossible to get a supply of milk, and the man vomited all else. Soon the captain confiscated the pajamas for other men on the ground, and after a few moments I gave him the money also.

After he had appropriated for his company all I had to give, he called the captain who had command of my dying boy, and again I heard the story of forced neglect. They both stated that there were that day from ten to twenty men in each company on the ground for whom there was no hospital accommodation.

It seemed intolerable that over one hundred men in one regiment should be thus treated in our great country, far away from any enemy, while thousands stood ready to aid them, and millions of money would have been poured out for their relief. In their small regimental hospital I found the cots so close together that one mosquito netting served for two, and in another tent the same crowded condition, but no protection from insects. The surgeon showed me some green netting that had been given which stained the skin so badly that he was not willing to use it on the men.

The water supply was in a two-gallon tin pail, well iced, but it was necessary to skim off the drowned flies before the patients had a drink.

The surgeon in charge was a faithful man and did all that lay in his power, but red tape made the procuring of supplies slow, and the kindest intentions could not make finished nurses from the men detailed from the ranks, especially as in most cases there were changes in the personnel from day to day, and many of the soldiers heartily detested the work.

I did not appreciate how frequently inferior men were placed in charge of hospital patients until I had a little man, named Pharaoh, from the Ninth New York Regiment, whose one idea seemed to be to aid the others. As soon as he was able to be out of bed he began to help, until he had positively to be kept from doing himself harm. I asked him one day why he did not do such work in the hospitals. He told me he had applied for such a position, but they said, "No, Pharaoh, no. You know how to march and do things. You are not the kind of man to be put into the hospital."

Dr. Clark, the major-surgeon of the Twelfth Minne-

sota, who did magnificent work in the Third Division Hospital, said to me: "I am doing all I can. The soldiers do not know how to do the work. Give me a dozen trained women and I will revolutionize this place. I have asked for them again and again, and have always been refused." Can you realize the difficulties under which he labored, when suitable drinking water had to be brought seven miles?

The Red Cross supplied ice abundantly, and I understood that with care there was enough for each hospital; certainly Leiter had plenty, though none to waste.

The oftener I visited the camp the more its natural advantages grew upon me, and I appreciated that for a smaller number of men and a limited period it might have been an ideal situation, but the unforeseen keeping of many regiments so long a time was a great cause of sickness. The rock came so near the surface that the heavy rains rendered what in dry weather were the most desirable camping grounds veritable swamps, and the difficulty of procuring pure water made many men careless of what they took. I asked one of my cavalry patients if he ever drank from the horse trough, and he said "Certainly," and that a large part of the men of his regiment did also, which carelessness would of itself explain much disease. They all confessed they were untidy in many ways, and disliked the work of keeping their camps clean.

As almost without exception the regimental officers were appointed by the governors of their respective States, the general government can not be blamed for much of the lack of discipline regarding sanitary matters, and in many instances the lack of supplies came through the ignorance of the officers regarding methods of securing them.

Too much can not be said against the army canteens as they existed at Chickamauga. Man after man told me that he could get any amount of moonshine whisky whenever he wished it, and that they had never heard of efforts being made to keep it out of camp. Raw corn whisky is one of the most injurious forms of liquor, and the soldiers frankly stated that they were sure much sickness could be traced to its use.

To give you a summary of my views as regards the nursing, I must say that never in our largest hospitals in Boston or New York have I seen more devoted care than was given by the women nurses to their patients, though from the climate, poor water, and necessary overwork, as high as seventeen nurses out of the forty at Leiter have been off duty at one time, and just before I left there were only twelve men of the hospital corps out of the forty-four at work. At one time we had four of them sick with typhoid fever in our ward. It was worth the toil and deprivations to hear the men say, as they did to me more than once, "We fellows think we've got to heaven when we've got to Leiter Hospital."
The most serious criticism I have to pass on the general management is that in so few instances were the nurses placed under a trained and responsible woman superintendent. Sternberg Hospital was favored for the fact that Miss Maxwell, acting under the authority of Dr. Anith Newcomb McGee, director of Daughters of the American Revolution Hospital Corps, selected her own nurses and looked after their interests from the first. Leiter, on the contrary, being opened months earlier, had nurses detailed there a few at a time, so there was never a definite head to that department, the steward looking after it in a general way in addition to his other duties. Though devoted and judicious, his work necessarily betrayed inexperience in that direction.

I was astonished to hear that there had been anywhere question as to the character of the nurses employed. Certainly at Leiter I never saw anything questionable, and I am sure that at Sternberg the same held good. A marriage between a nurse and assistant steward at one place and a corresponding engagement at the other could only be considered objectionable from the point of military discipline, certainly not of morals. There were many instances of friction between the Red Cross and contract nurses, which seemed to be almost a necessary result of trying to employ side by side persons engaged under different organizations.

I will here explain that those spoken of as Red Cross nurses had no connection with the National Red Cross Society, but were sent out by various auxiliaries that had many and diverse ideas as to qualifications. While the greater part did excellent work, it frequently seemed as though some rigorous army discipline would have increased the value of their services. While their employment seemed to many desirable for a time, there is no doubt but that when the army authorities are allowed to select all of the nurses in the field there will be a long forward step made.

There is to my mind no doubt that the work of the trained nurses was a godsend to the suffering soldiers. And I have reason to believe that when the plans contemplated are fully carried out there will be a great gain to the military service.

In conclusion, I wish Godspeed to the two hundred women who are to-day doing what they can for our soldiers. And let us remember that while many mistakes have been made much good has been done. Let us help where we can. Criticise only to aid, letting our highest love and service go out, even to death it may be, for God and our native land.

Note, October 23, 1899.—Medical officers returned from the Philippines tell me that the above statements apply equally to the nurses in this country and those employed across the seas. There are in and around Manila a large and increasing number of contract nurses whose discipline is excellent and their work well done. All agree that trained women nurses are a sine qua non in the advanced medical and surgical care of our soldiers.
ferred to me by Dr. Walter Keate, and the patient was
brought in a hundred and forty miles on the railroad.
When I saw him, on September 22d, there was still some
oozing of blood. This was checked by a firm bandage.
After three days, in which time the patient's condition
improved markedly, I operated. A quantity of blood
clots was removed from the scrotum. A deep silk
suture, introduced at the previous operation, had in-
cluded the cord, so the testicle was pulled up and ex-
cised. The inguinal canal and both rings were firmly
closed by deep sutures of kangaroo tendon. The skin
was sutured with silk-woven gut. The wound was already
slightly infected when I operated, and there consequent-
ly followed some suppuration, though not of a serious
nature. Firm union occurred in three weeks. Patient
discharged October 21, 1899.

Case III.—Mr. W. F. D., jeweler, aged twenty-nine
years, had a congenital hernia on the right side. Owing
to wrong diagnosis, he had elsewhere undergone a sub-
cutaneous operation for varicocele. He was referred
to me through the kindness of Dr. B. M. Hines, of
Alpine, Texas, who had correctly diagnosed the con-
dition. Operation was performed May 11, 1899. A
mass of omentum, about an inch in diameter, was found
firmly adherent to the testicle and cord. It was dis-
sected loose, more pulled down, and the whole amount
ligated in sections and cut away. The congenital sac
was split, removed from around the cord in the ingui-
nal canal, and then ligated at the internal ring, as in
the case of an acquired hernial sac. The rest of the
operation was finished after the method of Bassini.
The wound healed by first intention throughout. The
patient was discharged May 31, 1899. When he was
last heard from there was no evidence of recurrence.
The mass of adherent omentum, so intimately connected
with the cord and the testicle, had in some degree resem-
bled varicocele when the patient was standing.

REPORT OF
A CASE OF ACUTE LYMPhilAEIA OR
ACUTE LYMPHATIC LEUCÆMIA.
By WILLIAM N. BRADLEY, M.D.,
PHILADELPHIA.

From the standpoint of blood examination Cabot de-
dcribes three varieties of leucæmia: chronic myelocy-
tæmia, chronic lymphæmia, and acute lymphæmia.
The case I wish to report belongs to the class design-
ated acute lymphæmia. The disease occurred in a boy.

Reuben B., aged eight years; Hebrew parentage; a
native of New York; living in Philadelphia for the
past six months.
The following is the only family history of impor-
tance that could be obtained: Mother had suppurring
cervical glands when a child. One brother of the pa-
tient had marasmus, but recovered, and has since been
healthy. The patient had suppurring cervical glands
when a year and six months old, and measles when three
years old.
The present illness began about one week prior to
the first visit to my office, June 13th. He complained
then of loss of appetite, lassitude, and no desire to play,
and my attention was called to enlarged anterior cervi-
cal glands. On examination, I found the following:
The patient was pale, but not anaemic. The glands
were enlarged on both sides, each being about the
size of a goose egg; they were soft and elastic; each
gland could be isolated. Temperature, 100° F.; some
shortness of breath; no cardiac murmur; no cough; de-
cided dulness over apices, and upper and middle lobe-
of both lungs; harsh breathing, with prolonged expiration;
domabn enlarged; no pain elicited on pressure over
abdomen or left side. Acute pulmonary tuberculosis
was suspected.

On June 18th, five days later, there was no improve-
ment in his general condition; the glands, however, were
reduced in size. A brassy cough had developed, which
was worse at night; no expectoration. A week later,
June 25th, the condition of the patient being consid-
erably worse, a consultation was advised, at which time
the patient's condition was as follows: Anaemia pro-
nounced; dyspnoea decided; spleen greatly enlarged, be-
ing palpable two to three fingers' breadth below the
anterior border of the ribs; the liver slightly enlarged;
the epistomal, axillary, and inguinal glands were en-
larged.
The consultant made a tentative diagnosis of Hodg-
kin's disease until the blood could be examined. There
being no expectoration, I had been unable to examine
for tubercle bacilli.

The blood examination, kindly made for me by Dr.
Rosenberger, demonstrator at the Jefferson Medical
College, revealed the following: Red corpuscles, 1,850,000;
white corpuscles, 85,000; haemoglobin, eighteen per cent.
The proportion of red to white here was 1 to 22. Differential count: Large lymphocytes, sixty-nine per cent.; small lymphocytes, twenty-eight per cent.; polymorphonuclear leucocytes, three per cent.

Out of six hundred leucocytes counted no cosinophils were demonstrable.
The blood examination, of course, revealed the true
nature of the disease. From this time the history is
one of rapid failure in strength and progressive anaemia,
with all the accompanying symptoms. Cough and dysp-
noea became worse. A dark-red purpuric rash devel-
oped, covering the entire body. There was constant
oozing of blood from the gums and an occasional clot of
blood coughed from the bronchial tubes; subsequently
the cough almost ceased.
The day before death my notes give the following:
Strength fast failing; complains of legs hurting him,
but this, I believe, is due to the anaemia and not to any
myelogenic involvement, as there is no pain on pressure
over the bones, nor is there any oedema; refuses nour-
ishment; tongue pale; skin waxy and translucent; gums
very anaemic and bleeding; the submaxillary glands sud-
denly became enlarged and hard. There is now pain
over the abdomen, which is greatly enlarged, and over
the left side; still no cardiac murmur; the cervical
glands much reduced in size; dyspnoea very severe;
great restlessness; tendency to coma and irrational
when roused.
The bowels, throughout the disease, were slightly
loose, but without any tendency to diarrhoea.
The urine was light amber; the amount passed nor-
mal; no casts; and contained a large quantity of crystals
of calcium carbonate.
The patient died July 22d, less than eight weeks
having elapsed since the first intimation that the child
was ill.

No post-mortem was permitted.
A consideration of the case has impressed upon me the following: 1. The ease with which the onset may be mistaken for acute pulmonary tuberculosis. 2. The scrofulous family history. 3. The possible coexistence of tuberculosis. 4. The necessity of careful blood examination. 5. A predominance of the large degenerated lymphocytes seems to indicate the approach of a fatal ending. 6. The absence of granulation in the lymphocytes. 7. The extreme dyspnoea was due to enlarged bronchial glands. The number of red blood cells being reduced, the haemoglobin was necessarily reduced, hence the oxygen-carrying power of the blood was diminished. This in turn resulted in a diminished oxygenation of the blood, which acted secondarily on the respiratory centre, producing dyspnoea.

1322 South Sixth Street.

ASEPTIC SURGERY IN THE COUNTRY.

By R. L. WOODARD, M.D.,
HOPINSVILLE, KY.

In reporting these cases it is not my object to bring out anything new, but simply to emphasize, or rather to demonstrate, that aseptic surgery is possible under the most unfavorable circumstances.

At a meeting of the Southern Kentucky Medical Society last spring there was quite a lengthy discussion as to whether or not it was possible to do a thoroughly aseptic operation in the homes of the lower class of people. The argument was supported by able men on both sides, several men of large experience urging that they had never been able to get results claimed for aseptic work.

The following cases, while not enough to prove conclusively that the result can always be had, yet show that it is possible. All these operations were done in cabins of two rooms each, used by the entire family as kitchen, dining room, parlor, and bedroom. One was within ten feet of a railroad and within twenty feet of a gashouse, with all their attending odors and filth. The house itself was as dirty and filthy as could well be imagined, and the weather was unbearably hot, the mercury standing at 98° to 100° in the shade.

Case I.—Bettie B., negro, aged thirty-three years, married; mother of one child, twelve years old. Since the birth of her child, she has suffered from dysmenorrhoea and internal hemorrhoids (the hemorrhoids were removed two months before the abdominal section was done). She has always suffered from pain in the ovarian region, backache, headache, and pain radiating down the legs.

When I first saw her she was suffering from an acute attack of pelvic inflammation and was so tender that a thorough examination was impossible; she gave a history of repeated attacks of like character for the past five years. Gave her a saline purge and enough morphia to relieve pain, also ordered hot turpentine stipes and hot-water douches every four hours. Saw her again on the third day, and, on digital examination, found both ovaries prolapsed and enlarged, and firmly adherent to the uterus, which was slightly retroverted. General health fairly good.

Operation was advised and consented to. Gave a saline purge and ordered a good general bath the following morning. The next morning the abdomen was thoroughly scrubbed with soap and water, shaved, and again scrubbed with soap and water, with a 1-to-500 bichloride solution, and with ether. My hands and those of my assistants were washed with soap and water and thoroughly scrubbed with nailbrush, then washed in a 1-to-500 bichloride solution and with ether. My instruments were boiled in a soda solution and allowed to remain in this solution during the operation. None but flat sponges were used, and they, with the ligatures, were boiled just before the operation. The water used had previously been sterilized and was carried to the house in stone jugs.

The abdomen was opened by median incision; both ovaries were found prolapsed and firmly adherent; the adhesions were old and could not be broken up with the fingers, but were dissected off with scissors. All bleeding points were tied and oozing stopped by hot, flat sponges. The ovary was now brought into view, and found to be of four times the natural size and very much congested and enlarged. The ovarian artery was ligated with a single silk ligature; the tube and remaining vessels were ligated with a double silk ligature, and the ovary was removed. The other side was treated in the same way. The abdomen was sponged out thoroughly and the incision closed with single silkworm-gut sutures. Time of operation, fifty minutes. Patient reacted nicely; vomiting was controlled by cracked ice and whisky; suffered comparatively no pain, and took nourishment next day; moved bowels by enema on second day; urine passed without catheter. On the third day the temperature reached 100° F., which was the highest point ever reached, and after that it was never over 99° F.

Sutures were removed on the twelfth day and the wound found to be healed by first intention. Patient sat up in bed on the twentieth day and was walking around in the room on the twenty-eighth day. Now, two months after, she is attending to her household duties and is entirely well.

Case II.—Hannah E., negro, aged forty-six years, married, mother of six children. Has suffered for the past seven years with dysmenorrhoea, metrorrhagia, ovarian pain, and pain in the back, radiating down the legs. Has not had pelvic inflammation. On examination, the ovaries were found to be normal in size and position. The tube was enlarged and a swelling the size of a walnut was felt at the fimbriated end of the right tube and a number of smaller cysts were felt on the left side.

After preparing the patient as in Case I, I opened the abdomen by a median incision and removed a cystic tube from the right side and a number of small cysts from the left side. The cysts on the left side were on both the tube and ovary. The patient reacted well and made an uneventful recovery.

Case III.—Georgia H., negro, aged twenty-two years; mother of one child, ten months old. Gave history of having received a severe blow on breast four years ago. After the birth of the child an abscess formed, which was opened and healed, leaving the breast tender and enlarged. A tumor of the size of the fist could be felt, located in the centre of the breast, diagnosed as chronic abscess.
The breast was thoroughly cleaned and removed, and incision closed completely with silkworm-gut sutures. Healed by first intention. Patient never had a rise of temperature. Sutures removed on twelfth day; the wound found to be perfectly clean and free from pus. Made a complete recovery.

**HERNIA IN THE FEMALE.**

By THOMAS H. MANLEY, M.D.,
PROFESSOR OF SURGERY AT THE NEW YORK SCHOOL OF CLINICAL MEDICINE; VISITING SURGEON TO HARLEM HOSPITAL AND THE METROPOLITAN HOSPITAL AND DISPENSARY.

**HERNIA** presents many remarkable phases in the female sex. None of our authors on this infirmity have yet given this subject either adequate or systematic consideration. From whatever side we view the subject, we are impressed by the wide differences presented in the female sex.

In order, therefore, to comprehensively analyze these, structure and function must be considered as well as those other phases of the subject which have a more practical bearing. Causes of a sexual character come into operation in etiology here. Its clinical history, symptomatology, morbid anatomy, and therapy in themselves constitute a large chapter in surgical maladies.

**More Serious in Women.**—Hernia in the female, in early life, is less frequent than in the male; in advanced age it is the reverse. With women it is altogether a more serious infirmity than with men; more ineradicable to mechanical supports, more prone to strangulation, and is attended with a larger mortality after ketomy.

**Atypical and Complicated Hernial Conditions.**—Atypical and complicated ruptures are often encountered on dissection here; the hernial condition, in consequence of physiological demands, is essentially feminine; and the vaginal hiatus through the pelvic floor, in conditions of visceral ectopia, often permits of a concealed displacement of the internal organs of generation, and sometimes other structures.

The protracted pressure of the excessively distended uterus may not only weaken but quite totally destroy the muscular supports of the abdomen, leaving a hernial condition commonly designated "pot-belly"; moreover, the throes of labor, with the convulsive, tetanic contractions of the muscles, sometimes produce median diastasis, a laceration or partial sundering from the osseous attachments of the muscles.

**On the Influence of Pregnancy in Producing, Aggravating, or Strangulating Hernia.**—If we exclude exomphaloecele, we have no evidence from any source that normal pregnancy in any manner tends to the development or aggravation of an aperture hernia—i.e., an extrusion through any of the canals of emergence; nor can any recorded authentic case be found wherein the parturient act led to strangulation. We may, accordingly, quite entirely disregard ordinary rupture as constituting any physical impediment to marriage. On the contrary, some authors, who have made a special study of this phase of the subject, affirm that, while in early pregnancy there may be some augmentation in volume of the extrusion, not infrequently before the time of delivery the hernia may become much diminished or have entirely disappeared.

**Mortality in Operations for Hernia in the Female.**—The female peritoneum bears invasion and operative manipulation with a notable tolerance, the mortality after laparotomies being much less than obtains in the male sex. Pathological lesions, too, within abdominal serous cavities of women are frequently tolerated with greater impunity and less disturbance than is the same class of lesions in men. But when intestinal stenosis from hernial obstruction occurs in women we observe a radical departure, as with them the onset is usually more sudden, the symptoms are more acute, more ominous and alarming, strangulation speedily paralyzing the centres of life, and quickly cutting life short, if intervention is not prompt and judicious.

The operative mortality for strangulation is large; before the days of early ketomy and antisepsis it was appalling.

Profound pulmonary narcosis and incomplete or imperfect operation augments the death-rate. The wide, open incision, made early, with the substitution of local cocaine analgesia in appropriate cases, will save many who otherwise must perish, through the only possible means available for preserving life.

**Ventral Hernia and the Drainage Tube.**—The frequent recourse to celiotomy for the exploration or treatment of pelvic lesions, and the employment of drainage tubes or large twists of gauze in the open wound, resulted in very frequent post-operative ventral hernia, a condition, Mr. Bland Sutton very truly observes, not infrequently much more painful and distressing than that for which the original operation was performed.

A large incision through the abdominal walls is no more conducive to a later evantuation than a smaller one; nor does my experience convince me that protracted recumbency in bed after the operation exercises any special influence as a prophylactic measure. The tendency to this hernia, then, is not so much dependent on whether we make a small opening or split the muscles instead of cutting them, as it is on an improper approximation of them and of the peritoneum. But a laparotomy, however performed, always leaves a breach closed in by scar tissue, a substance prone to yield and favor rupture. To remedy this defect, or provide against overstrain, every patient laparotomized, for some time after should wear a broad, circular support over the abdomen.

**Surgical Therapy in Female Hernia.**—The rules laid down for the operative treatment of rupture in
the male must be widely deviated from when the inguinal areas are the seat of lesion in the female. Her inguinal canal is but an almost invisible slit; the round ligament but a rudiment, sometimes absent. However, inguinal hernia, when it does occur in the female, usually produces a wide breach in the abdominal walls at the site of emergence.

Feminine hernia of every type, unattended with organic changes, or complicated by serious internal disease, should be treated by surgical intervention. As this is quite invariably free from danger in the non-strangulated, and the prospects of permanency in effects are greater than in the male, it may be generally recommended.

For the “hernial condition,” the wide diastasis of the median raphe, or extensive atrophic changes in the lateral muscles of the abdominal walls, with the resulting “pot-belly,” surgery can accomplish little if anything. The treatment of this infirmity must be prophylactic. The pregnant woman with a marked tendency to a sagging forward of the abdominal walls should be girdled up by a properly adjusted circular support; and when labor is violent or very protracted, muscular overstrain should be relieved by the use of the forceps or manual support of the overstretched abdomen.

SOME CONSIDERATIONS REGARDING THE CLIMATIC TREATMENT OF TUBERCULOSIS.

By F. E. WAXHAM, M. D.,
Professor of Medicine and Laryngology, Medical Department, Colorado University.

The greater one’s experience, the more convinced he becomes as to the benefit derived from the climatic treatment of tuberculosis. The climate must be adapted to the patient, as in the case of all other remedies. There is no climate suitable to all cases any more than one medicine is suitable to all diseases, but that early cases of tuberculosis are greatly benefited or entirely cured is beyond dispute. I would that my words might reach every practitioner far and wide when I repeat what I have often said before: “Send your tuberculous cases westward, and send them early.” The advice to seek health in a change of climate should be the first advice given, and not the last resort after months of futile treatment. It must be taken for granted that there are cases—those without the means with which to travel and to command the comforts of life—that are not proper subjects for climatic treatment unless by some great philanthropy they can be colonized and cared for free from expense until they are cured and become self-supporting. As intimated before, the secret of success lies in the early diagnosis of the disease and in early seeking a change of climate before the golden opportunity of regaining health has passed. In order that a patient may be given the best chance of life, a correct and early diagnosis must be made. To detect tuberculosis in the very early stage is not an easy task, and often requires the greatest skill and the most careful and thorough examination by the physician. Too frequently a hasty examination is made through the clothing and the case pronounced one of bronchitis, and so treated for mouths, sometimes until recovery from climatic treatment is beyond all expectation. I would plead for more careful and thorough examinations, not by experts and specialists, but by general practitioners. I would insist upon the necessity of stripping the patient to the waist, and upon the minutest examination by mensuration, palpation, percussion, and auscultation, and also upon repeated microscopic examinations of the sputum. Only by these methods can an early and accurate diagnosis be made. I fully believe that the use of the microscope by the general practitioner is not sufficiently common. In this day of post-graduate schools every practitioner of medicine should be fully equipped with a microscope and skilled in its use. Let me repeat, the benefit derived from the climatic treatment of tuberculosis depends in no small degree upon the ability of the physician to make an early diagnosis and to act accordingly.

The idea that tuberculous individuals should be excluded from this State is being promulgated to a certain extent. If I am correctly informed, California has already taken steps to prevent the influx of consumptives, and the same plan is being entertained in Colorado. It undoubtedly is true that cases of tuberculosis developing in Colorado are more frequently met with than formerly, but it must be remembered that the population is much greater. It may be a question whether these spontaneous cases are more common in proportion to the population than formerly, but if so we should insist upon more thorough and vigorous measures of prevention and not upon restriction. The glorious climate of the West and Southwest should forever be open to tuberculous patients in search of health. Prolonged life and the blessings of restored health should not and must not be denied by crazy legislation inspired by fear and cowardice. To deny health and strength and life to those in search of them for fear, perchance, that we may contract their disease is selfish, and in this day of preventive medicine is unnecessary, unscientific, and unworthy of a Christian people. If we fear the spread of tuberculosis, then let us teach the methods of prevention, and, if necessary, by legal enactments enforce these measures, but in the name of humanity let us not interfere with the coming of these health-seekers to our glorious climate. Undoubtedly the reason that inspired the prejudice in California against consumptives has been the large number of patients that have sought that climate in the very latest stages and without adequate means of support. They have received little or no benefit from the climate and have soon become a burden upon the community. That “patience should
cease to be a virtue” after long suffereance is not difficult to understand. Let us, however, with patience, and yet with all the emphasis at our command, cry out against this custom of sending invalids in the last stages of consumption from the comforts of home and friends to die in a distant land among strangers, and instead let us bid them come early and assure them of complete recovery.

In the climatic treatment of tuberculosis there is one feature that should not be overlooked, and that is the importance of rest and increased nourishment. Too frequently patients are advised to take little or no medicine upon arriving in this country, but to take abundant exercise. This is often a great mistake, especially regarding exercise. Invalids, instead of exercising when first coming to a great altitude, should take long hours of rest, and if there is any fever the repose should be absolute until the fever has subsided. This in connection with greatly increased nourishment will give the best of results. Other necessary factors are sunshine and outdoor life. If unable to exercise, tuberculous invalids should sit or lie out of doors as much as possible. Medicines have their uses and are of much importance, but the greatest factors in the cure of tuberculosis are rest, nourishment, altitude, and sunshine.

---

**Therapeutical Notes.**

Ointment of Yellow Oxide of Mercury.—Schanz (Lyon médical, August 20th) recommends the following formula:

- R: Yellow oxide of mercury, recently prepared ...from 15 to 30 grains;
- Lanolin .......................... 15 “
- Distilled water .......................... 15 “
- American vaseline .......................... 150 “
- M.

For Chlorosis.—Riforma medica for November 16th gives:

- R: Lactate of iron .......................... 1½ grain;
- Phosphate of calcium ................. 3 grains.
- M. For one powder. Three to be taken daily.

Trikresol in Alopecia Areta.—According to the Therapist for November 15th, Dr. Granville MacGowan considers trikresol a more effective remedy than any other. He has used it in nine cases with an average cure in two months and a half. His directions are briefly as follows: Cleanse the area thoroughly with benzene. Apply trikresol pure to the scalp. It is to be well rubbed into the denuded patches and into the roots of the hairs half an inch beyond each patch, by the friction of a small swab of cotton tightly wrapped on a wooden toothpick. The burning and pain are well borne and soon pass away. These applications are to be made somewhat irregularly, according to the particular local effect produced, but probably, on the average, every five to seven days, until the desired result is obtained.

The Hypodermic Use of Orthoform.—Dr. Florentino A. Loza (Anales de Sanidad Militar, October) says that the formula used in the military hospital at Buenos Aires for associating the analgetic action of orthoform with calomel used hypodermically in syphilis, is as follows:

- R: Oil of vaseline ............... 150 grains;
- Calomel ................................ 67 ½ “
- Orthoform ................................ 12 “
- M. From fifteen to thirty drops of this preparation have been used without signs of intolerance or intoxication.

Lutaud’s Disinfectant Injection for Leucorrhœa.—The Riforma medica for November 11th gives the formula as follows:

- R: Potassium chlorate .......... 12 parts;
- Sydenham’s laudanum (wine of opium) ........... 10 “
- Tar water .................................. 300 “
- M. Two or three teaspoonfuls to be added to a quart of warm water for vaginal irrigation.

Ferruginous Enemata in the Treatment of Chlorosis.—Jolasse (Presse médicale, October 4th; Lyon médical, October 22d) remarks that iron can not be given by the mouth to advantage until the digestion has been improved. In a number of cases he has used the citrate, in doses of from a grain and a half to nine grains three times a day, in the form of enema (the amount of water or other solvent not stated). The injection causes rather sharp pain, but it rapidly subsides.

Chloroform Water in the Gastro-enteritis of Children.—Van Emelen, of Antwerp (cited in the Presse médicale for October 18th), has employed the following prescription with success:

- R: Lactic acid ............... 15 grains;
- Chloroform water (1 to 200). 1,200 “
- Oil of chamomile ............... 2 drops;
- Syrup of anise .......................... 300 grains.
- M. S.: A tablespoonful every two hours.

Dormiol, a Hypnotic.—Journal de médecine de Paris for October 28th says of dormiol that it is a combination of chloral hydrate with amylene hydrate, liquid, colorless, oily, with camphoraceous odor. Density, 1.24. Soluble with diffiency in water, freely in alcohol, ether, and fatty acids. It has been administered as a hypnotic in a dose of seven grains and a half, but this dose may be increased to fifteen or even thirty grains. It may be prescribed in oil or in capsules. Meltzer’s formule is:

- R: Dormiol, mucilage of gum arabic, 1 of each. 150 grains;
- Syrup, Distilled water ............... 1,800 “
- M. Shake vigorously before administering. A soup-spoonful contains fifteen grains of dormiol.

For Infantile Cholera.—Presse médicale for August 16th attributes the following to Hayem and Lesage:

- R: Lactic acid ................ 45 grains;
- Syrup of quince ................ 37 ½ “
- Distilled water ............... 1,500 “
- M. The solution should be fed. A coffee-spoonful to be given every half hour for three hours, then every hour. Its use must be stopped as soon as the use of milk is resumed.
THE NEW YORK MEDICAL JOURNAL.
A Weekly Review of Medicine.
Published by D. Appleton and Company. Edited by Frank P. Foster, M.D.

NEW YORK, SATURDAY, DECEMBER 28, 1889.

POINTS ABOUT THE NEW PHARMACOPEIA.

Dr. Charles Rice, an eminent pharmacist, an active and painstaking member of the committee of revision, a man of exceptional common sense, and a remarkably clear writer, contributes to the December number of the American Journal of Pharmacy an article in which he deals with some of the problems that confront the committee. He makes three recommendations. The first is that the committee be authorized to introduce statements of doses into the Pharmacopœia, the details to be left to the committee’s discretion. There can, we think, be no question that their introduction would serve a good purpose; certainly it could do no harm. For years the Deutsche Pharmakopœa has given doses, and the recent issues of the British Pharmacopœia have given them, and in consequence those books have been pro tanto more useful to physicians than the United States Pharmacopœia, and doubtless to many retail pharmacists also.

Dr. Rice’s second recommendation is that the committee be authorized to introduce such of the “newer remedies” as fulfill certain requirements. If the remedy is a definite chemical compound, such as antipyrine, aristol, chloralamide, phenacetine, salophene, sulphonal, and trional, its chemical composition should be known and controllable. Moreover, it should have passed the experimental period and be regular and general use by the medical profession as a remedy of definite and recognized therapeutic value. Dr. Rice declares it an “ethical riddle” that men should use certain proprietary drugs freely in their practice, write of them in journal articles and text-books, and talk about them in their lectures and at medical meetings, and yet object to their recognition in the Pharmacopœia—and we quite agree with him.

The final recommendation is that the committee be instructed to extend the principle of standardization to as many of the potent drugs and their preparations as may be found susceptible of such treatment, but that at present no physiological tests be made official. Dr. Rice does not, indeed, object to the physiological method of testing the strength of a drug or a pharmaceutical product; on the contrary, he regards it as highly commendable on the part of some of the large manufacturing houses that they have resorted to it, but, since at present there is a lack of uniformity in estimating physiological tests, they had better not be made official until that lack of uniformity has been done away with. “Who,” he pertinently asks, “shall standardize the standardizers?”

All these recommendations of Dr. Rice’s commend themselves to our approval, and we think we can add one that, if carried out, would make the book much less of an enigma than it is at present to those physicians and pharmacists who are no longer young. We mean the restoration of the dear old system of grains, drachms, ounces, etc. It may not be quite “up to date” from the recent graduate’s point of view, but we are sure it would touch the heart of many an elderly man to see it restored—not to supplant the metric system, but to supplement it.

THE SUN FEVER OF TROPICAL AMERICA.

The term sun fever has been applied to a number of different pathological conditions. For example, dengue has been called by that name, so has sunstroke, and Aitken, in his Science and Practice of Medicine, uses it in connection with a febricula that is observed in Burmah and in India. According to Dr. William Hemphill Bell, of the navy, who writes on board the Vixen, stationed at Bluefields, Nicaragua (University Medical Magazine, November), the term is applied par excellence by the people of Central America, including the physicians, to a peculiar febrile affection of which he has observed five examples. It begins with a brief initial stage of pronounced malaise, a feeling of fullness in the head, and slight fever. These symptoms soon become aggravated and are accompanied by supraorbital headache, inflammatory swelling of the face, particularly about the eyes, hyperemia and œdema of the conjunctiva, soreness of the eyeballs and their sockets, impairment of vision, and more or less photophobia. At the height of the fever, about the second day, the temperature is between 102° and 103° F., and at that time the patient complains of soreness of the back and legs, with dull aching and diffuse tenderness of the abdomen, which seem to proceed from the stomach. There is atony of both that organ and the intestines, the tongue is swollen, flabby, and lightly coated, there is almost complete loss of appetite, with considerable tympanites, gaseous eructations, flatulence, and a tendency to constipation. This acute stage lasts ordinarily only six or seven days. It is thought not to be dangerous to life or to give rise to annoying sequelæ, but it
is surprisingly exhausting, so that a tonic treatment should be employed for several weeks. Unlike insolation, the sun fever of Central America does not leave its victim more sensitive than before to the pathogenic action of the sun; indeed, it seems to protect him against it in a measure.

As to the pathology of the disease, Dr. Bell is inclined to think that it is essentially a peripheral neuritis of a low grade, limited to the parts exposed to the direct action of the sun, with resulting vasomotor paralysis and oedema of the deep tissues of the inflamed area, whether cutaneous or mucous. He thinks the gastrointestinal disturbances and the moderate fever are the consequences of this inflammation. Although he believes the sun's rays are the actual cause of the disease, it is not by mere heat that they act, for nothing of the sort results from exposure to the intense heat of the fire room. "There seems to be some special element in the solar spectrum," he says, "such as suggested by the phenomena of the Röntgen ray, capable of injuriously affecting the tissues," and he calls the disease a "sun traumatism." He notes that all his patients were of the very blond type, and he thinks that all persons of light complexion, if they have not gradually become inured to exposure to the tropical sun, are susceptible to this disease.

Much as the medical officers of the British services in India and other hot regions have done to increase our knowledge of tropical diseases, Dr. Bell thinks they have not made the most of their opportunities. Doubtless this is true; most men fall short of their full capabilities. Let us endeavor, in the new possessions that have come to us recently, to do better; nevertheless, if we but do as well as our British brethren have done, we need not be ashamed. That we shall do so, Dr. Bell’s very valuable communication is an earnest.

AN EPIDEMIC OF RABIES IN JAPAN.

In the Archiv für pathologische Anatomie und Physiologie und für klinische Medicin, vol. clviii, No. 1, Professor Tomei Kurimoto, of Nagasaki, gives an interesting account of his having, under considerable difficulties, established an efficient Pasteur protective-inoculation service in Nagasaki, and recounts an epidemic of rabies which occurred some time ago in the district of Minamitakaki, on the peninsula of Shimabara. From the first of January, 1894, to the tenth of March, 1895, he observed sixty-seven persons who had been bitten by rabid animals, but were not subjected to the Pasteur treatment. Twenty-one of them died, and the others survived. The percentage of deaths, therefore, was 31.34, against a mortality of not more than half that figure in France. The author remarks that the mortality varies in different countries, and he brings up the question of whether or not the virus of rabies is more potent in Japan than in some other lands, but declares that he is unable to answer it. He suggests, however, that numbers of persons whose bites were not severe, but some of whom undoubtedly died of rabies, failed to report, and that thus the apparent rate of mortality was made to exceed the real rate.

Such was the fate of those who went without the Pasteur treatment. The author’s subsequent experience with that treatment was more fortunate. From August 12, 1894, to February 25, 1899, 254 bitten persons were treated in his institute, of whom only thirty-two died. Of these thirty-two, twenty-nine left the institute too soon, before the treatment was finished; one was already affected with the disease when he entered, and died the next day; another was attacked on the day after his admission, and died the next morning; and the remaining patient died after fourteen days of treatment. That left 222 persons who underwent the Pasteur treatment to its full extent, and of those, only four died of rabies. While the author admits that there is no remedy, not even the inoculation treatment, that can be depended upon to prevent rabies when once the virus has had access to the central nervous system, he maintains that these figures afford a striking contrast to those in which he records the results of bites in persons not subjected to the Pasteur treatment. As there has been a tendency for the last few years to decry the inoculation treatment, and even to charge it with causing a certain number of deaths from rabies, it seems timely to call attention to Dr. Kurimoto’s experience and to urge anew the importance of the early and thorough employment of the Pasteur treatment of persons bitten by rabid animals.

THE SANCTITY OF PROFESSIONAL CONFIDENCE.

It is hard for us in this country, where the law not only upholds the sanctity of professional confidence, but absolutely makes its breach punishable, to grasp such a condition of things as is evidenced in the Lancet for November 18th as having occurred at Southpost in England. An infant having been found dead, and medical evidence showing that it had had a separate existence and that its death was due to exposure, the chief constable saw fit to address a letter to the local medical men, informing them of the facts, and adding: "As it is not unlikely that the mother may be requiring medical attention, I should be obliged, should any suspicious case come under your notice, by your communicating with me at once." A conference of medical men was
thereupon called, and a protest was framed against this objectionable notice, which in this country would be held not as an incitement to aid in the discovery of crime, but as an incitement to crime itself. The deputy coroner and the jury, however, indorsed the constable’s action and condemned the protest of the profession, the coroner being of opinion that “the medical gentlemen of the borough would have been anxious to assist the prosecution.” The *Lancet* very naturally supports the profession by pointing out that if medical men were to become state spies patients would refuse to seek professional aid, and many lives would be jeopardized thereby. The further and personal objection urged by the *Lancet*, that the medical man, by communicating his suspicions to the police, might make himself the object of unjust opprobrium and, if mistaken, subject himself, moreover, to loss of professional prestige and to serious monetary reprimands, seems to us an unnecessary and unworthy addition. The point of view taken by the authorities is brutal and unworthy of a civilized country—and that consideration alone should be reason enough.

---

**THE ARCHIVES OF PÆDIATRICS.**

It is announced by the editor, Dr. Floyd M. Crandall, in the December number of this excellent journal that the growth of his other work constrains him to retire from the editorial management of the *Archives*. Dr. Crandall has done a great deal to bring that journal to its present high position in the esteem of the profession, and whatever prosperity may come to it in the future—and we hope and believe it will be abundant—will in no small degree be traceable to his efforts. Dr. Walter Lester Carr is to succeed Dr. Crandall as editor of the *Archives*, and we do not doubt that he will conduct it creditably and successfully.

---

**THE LOST SPONGE.**

The serious error of unwittingly leaving a sponge in the abdomen after abdominal section is still occasionally committed, notwithstanding the thorough appreciation of the danger by surgeons. Considerable publicity has been given to an instance that lately occurred in one of the hospitals of Columbus, Ohio, which formed the text for an excellent article published in the *Columbus Dispatch* for November 22d. It appears probable that in that case the fault lay partly with the person who was charged with making packages of a definite number of sterilized sponges, for there was testimony to the effect that on more than one occasion a package had been found to contain a supernumerary sponge. The unfortunate occurrence in Columbus emphasizes the importance of not trusting altogether to the package-maker’s count; for her own protection, if for no other reason, the nurse in charge of the sponges should count them anew at the outset of each operation.

---

**THE DIPHTHERITIC BACILLUS IN THE HEALTHY MOUTH.**

The occasional existence of the bacillus of diphtheria in the mouths of persons who are perfectly healthy can only with extreme rarity, it appears to us, lead to a mistaken diagnosis of that disease. Dr. Kober (Zeitschrift für Hygiene und Infektionskrankheiten, 1899, No. 3; Presse médicale, September 13th) has shown, indeed, that the current assumption that Löfler’s bacillus is to be found in the mouths of eighteen per cent. of the healthy persons who have been in contact with diphtheria patients is too sweeping; he finds it in only eight per cent.

---

**LUMBAR PUNCTURE IN OTTIC MENINGITIS.**

The idea that lumbar puncture may be serviceable not only in confirming the diagnosis of meningitis due to purulent otitis, but also in contributing to the patient’s recovery, seems to Dr. Alfonso Bormans (Gazzetta degli ospedali e delle cliniche, July 30th; Gazette hebdomadaire de médecine et de chirurgie, September 10th) to have been borne out in two cases reported by him. The fluid withdrawn was turbid and contained staphylococci. After an operation upon the tympanum and the mastoid the patients recovered, and their recovery appeared to have been partly due to the puncture.

---

**HYPNALGIA.**

Among the curiosities of the pathology of the nervous system is probably to be classed a morbid manifestation to which, at a meeting of the Berlin Society of Psychiatry and Neurology (Gazette hebdomadaire de médecine et de chirurgie, October 26th), Dr. Oppenheim gave this name. Those who are affected with it, mostly neuropathies, have no pain while they are awake, but on going to sleep are awakened by pain behind the sternum, in the occipital region, or in the neighborhood of the kidneys. The pain soon subsides, only to recur on their going to sleep again. It seems sometimes to be connected with some change in the innervation of the heart or the lungs.

---

**THE INDISPENSAIBILITY OF THE LABYRINTH TO THE POWER OF HEARING.**

Some cases have been reported of the apparent persistence of a trace of auditory power after destruction of the labyrinth on each side, but Dr. Kamm (Haug’s *Sammlung klinischer Vorträge*, iii, 3; Centralblatt für innere Medizin, November 15th) has been led to conclude from experimental observations that, while it is conceivable that some power of audition may remain after the destruction of both cochleae, there is no vestige of it if both labyrinths have been wholly destroyed.

---

**AN OPERATION FOR THE “IRRITABLE TESTIS” OF SIR ASTLEY COOPER.**

Some years ago most of our surgical text-books in English recognized no name but Sir Astley Cooper’s term “irritable testis” for an affection manifested by severe and persistent pain in the testicle without organic disease of that organ. Valleix called it lumbo-abdominal neuralgia, and he thought it essentially identical with a painful affection occasionally observed in women in which the pain was referred to the labium majus. Orchidecotomy does not always cure it permanently when it occurs in men, and is open to some other objections; moreover, less radical procedures often prove effective, although in an obstinate case reported by Dr. Julius Donath and Dr. Fidelis Hüttl (Wiener klinische Wochenschrift, 1899, No. 11; Monatsshefte für praktische Dermatologie, October 1st) resection of the lumbo-inguinal and external spermatic nerves did not
survive for a perfect cure. The pain returned at a late date after the operation, but it was much less severe than before. It is noted that the sexual appetite was decidedly augmented after the neuroectomy.

PRECAUTIONS FOR THE BENEFIT OF PERSONS BURIED ALIVE.

For years the physicians of France have given a great deal of attention to the prevention of burial before death. Now their efforts seem to have been directed to means of enabling a person who has actually been buried alive to call for assistance in case he recovers consciousness or makes any movement. Ingenious devices to achieve the purpose were recently demonstrated in New York by two French gentlemen. They included a slight illumination of the interior of the coffin through a tube communicating with a lamp, also a button which, when being touched, would set off a rocket, sound an alarm, and send a signal to a general telephone station. We are very skeptical about the occurrence of ante-mortem burial, and the long experience of the mortuary chambers in Munich seems to justify skepticism, but there are many good people who live in an agony of dread lest they may be buried alive, and for the sake of their peace of mind such efforts as we have mentioned should be encouraged.

A NURSES' TRAINING SCHOOL IN HAVANA.

The September number of the Habana Médica announces its gratification at the foundation of a training school for nurses in Havana, and we wish to add our congratulations to the profession of that city, where there is doubtless a large field for skilled nursing.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported for the two weeks ending December 16, 1890:

Christian Greece and the Living Greek.—We understand that Dr. Achilles Rose's book bearing the foregoing title has reached a second edition in the Greek translation, 'Η χρωστικήν Ἐλλάς καὶ η ζωή τῆς Ελληνική γλώσσα, ὑπὸ Ἀρενίου Ῥοζ ἐκ τῆς ἀγγειών μετεργασθὲν εἰς τὴν ἐλληνικὴν ὑπὸ Μακρυ Κωνσταντίνου. The German edition has been recently published and favorably noticed in both the medical and lay press, while a French translation goes to press after New Year's.

The Buffalo Academy of Medicine.—At the last regular meeting of the Section in Pathology, on Tuesday evening, the 19th inst., the following papers were presented for discussion: Meckel's Diverticulum, with exhibition of specimens, by Dr. Irving M. Snow; and Diseases of the Middle Ear requiring Radical Treatment.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, and plague were reported to the surgeon-general during the week ending December 15, 1890:

An Examination for the Medical Corps of the Marine-Hospital Service.—A board of officers will be convened at the Service Building, 378 Washington Street, New York, on Wednesday, February 7, 1900, for the purpose of examining candidates for admission to the grade of assistant surgeon in the United States Marine-Hospital Service. Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character. The following is the usual order of the examination: 1. Physical. 2. Written. 3. Oral. 4. Clinical. In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate. The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination on the-
The Late Dr. Charles Inslee Pardee.—At a regular meeting of the board of directors of the Manhattan Eye and Ear Hospital held on November 21st, the chairman, Mr. George E. Sterry, vice-president, called the board's attention to the loss the hospital had suffered in the death of Dr. Charles Inslee Pardee, and on motion appointed Dr. Roosa and Mr. George G. Moore a committee to draft suitable resolutions.

Dr. Roosa remarked that he had been a classmate in the medical college with the late Dr. Pardee, and that he had been intimately acquainted with him from that time until the day of his death. His death was very sudden, said to be from apoplexy. After graduation, Dr. Pardee served gallantly and efficiently as a medical officer in the volunteer service during the civil war. On his return, he was associated with Dr. Roosa in the University Medical College, and, as his assistant, he was with the speaker on the opening of the Manhattan Eye and Ear Hospital, and served there as an assistant surgeon on the very first day that Dr. Roosa's clinic was opened for the reception of patients. He was elected surgeon in 1879 and continued his duties there until he was appointed dean of the medical faculty of the university. His labors in the medical college were so exacting that he was obliged to resign his position as surgeon of the Manhattan Eye and Ear Hospital. But, on the nomination of the late Dr. Agnew, he was made a director of the hospital, in which position he served with punctuality and faithfulness until his death. Dr. Pardee was an astute and skillful practitioner, and he was so successful as dean of the medical faculty that the speaker had heard the late Chancellor Crosby say he was worthy to be made chancellor of the university. He was very genial and interesting in social life, and, as had been said by the chairman of our board, we all deplored his loss.

The board of directors of the Manhattan Eye and Ear Hospital record with profound regret the death of their late colleague, Dr. Charles Inslee Pardee. Dr. Pardee was appointed assistant surgeon at the Manhattan Eye and Ear Hospital in 1889, and promoted to the surgeonship in 1879. He resigned the latter position on the 17th of November, 1883, and was thereupon elected a director of the hospital, which position he continued to occupy until the day of his death. He died on the 3d of November, and the board of directors make this record of his services to the institution, which were always of a high order. It is directed by the board that a copy of this be sent to the family of the late Dr. Pardee and to the medical journals.

[Signed.] JOHN SINCLAIR, President,
A. G. AGNEW, Secretary.

The St. Louis Medical Society.—At the last meeting, on Saturday evening, the 16th inst., Dr. Jerome K. Bauduy read a paper entitled A Comparatively Rare But Important Form of Syphilitic Neuralgia, and its Treatment.

Changes of Address.—Dr. William H. Roe, to No. 175 Nostrand Avenue, Brooklyn; Dr. H. Marion-Sims, to No. 101 East Sixty-first Street, New York; Dr. Floyd Stewart, to No. 5301 Franklin Avenue, St. Louis.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 9 to December 16, 1899:

HARTNETT, EUGENE H., First Lieutenant and Assistant Surgeon, United States Army, will report to the commanding general of the First Division and proceed to San Isidro, Luzon, for duty with the Fourth Cavalry, relieving GRANDY, LUTHER B., Captain and Assistant Surgeon, Thirty-fifth Infantry, who will proceed to Manila.

MAZZURI, PAUL, Acting Assistant Surgeon, United States Army, will report to the commanding officer, detachment of the Second Cavalry, for duty with the troops of that command while on practice marches.

SUMMERSALL, W. B., Acting Assistant Surgeon, United States Army, will report to the surgeon in charge of the Military Hospital in Matanzas for duty.

POWELL, JUNIUS L., Major and Surgeon, United States Army, will proceed to San Isidro, Luzon, for duty as division surgeon, relieving PENROSE, GEORGE H., Major and Brigade Surgeon, United States Volunteers, who will report to the commanding general, Third Brigade, First Division, for duty as brigade surgeon.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending December 16, 1899:

BELL, W. L., Assistant Surgeon. Detached from the Philadelphia and ordered to the Independence.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending December 14, 1899:

OAKLEY, J. H., Passed Assistant Surgeon. To proceed to New York and report to Surgeon L. L. WILLIAMS (Immigration Depot) for special temporary duty. To proceed to Queenstown, Ireland, for duty.
Wickes, H. W., Passed Assistant Surgeon. To proceed to New York and report to Surgeon L. L. Williams (Immigration Depot) for special temporary duty.

To proceed to Glasgow, Scotland, for duty.

Greene, J. B., Passed Assistant Surgeon. To proceed to Bremen, Germany, for duty.

Mathewson, H. S., Assistant Surgeon. To proceed to New York and report to Surgeon L. L. Williams (Immigration Depot) for special temporary duty.

To proceed to Liverpool, England, for duty.

Corput, G. M., Assistant Surgeon. To proceed to Maconville, France, for duty.

King, W. W., Assistant Surgeon. Detailed as inspector of unserviceable property at New Orleans.

McIsaac's Fire, Acting Assistant Surgeon. Granted leave of absence for two weeks from December 21st.

Society Meetings for the Coming Week:

MONDAY, December 25th: Medical Society of the County of New York; Lawrence, Massachusetts, Medical Club (private); Cambridge, Massachusetts, Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, December 26th: New York Dermatological Society (private); Metropolitan Medical Society, New York (private); Buffalo Academy of Medicine (Section in Obstetrics and Gynecology); Richmond, Virginia, Academy of Medicine and Surgery.

WEDNESDAY, December 27th: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Philadelphia County Medical Society.

THURSDAY, December 28th: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopaedic Society; Brooklyn Pathological Society; Brooklyn Society for Neurology; Roxbury, Massachusetts, Society for Medical Improvement (private); Pathological Society of Philadelphia.

Births, Marriages, and Deaths.

Died.

Bradfield.—In Fort Ontario, New York, on Saturday, December 9th, Marie Bradfield, wife of Dr. George M. Bradfield, United States Army.

Brechin.—In Boston, on Sunday, December 10th, Dr. William Pitt Brechin, in the forty-ninth year of his age.

Phares.—In East Feliciana, Louisiana, on Sunday, December 10th, Dr. John H. Phares, in the sixtieth year of his age.

Letters to the Editor.

A CRITICISM ON DR. KEMP'S ARTICLE ON THE EFFECTS OF DIFFERENT ANESTHETICS ON THE KIDNEYS.

225 West Forty-fifth Street,
New York, December 4, 1889.

To the Editor of the New York Medical Journal:

Sir: As an anesthetist, I think some remarks in reference to Dr. Kemp's article will not be without interest. A careful study of the paper must convince any fair-minded person that its tendency is to prove either a less safe anesthetic than chloroform, particularly when in the cases mentioned almost entirely the one anesthetic was given. One need but review medical literature to note practically the same experiments and deductions, which do not in the least detract from the value of ether as an anesthetic. Dr. Kemp admits it is possible for a chill to cause a congestion of the kidneys; he seems, however, to forget or ignore the fact that when a patient is operated upon more or less shilling, in spite of every precaution, is very apt to occur. The patient may be warmly protected, yet, for instance, an abdominal operation: the patient passes through various scrubings and irrigations, usually ending with alcohol and ether, both of which on evaporating extract considerable heat from the body. I am perfectly willing to admit that this is unavoidable, yet, should kidney disturbance follow, the anesthetic is charged with it forthwith. Kidney disturbance, even to complete suppression of urine, can occur where no general anesthetic has been administered.

As an illustration, some years ago, when I was an intern in a hospital in this city, a patient was operated upon for an external urethrotomy in which cocaine was used; the urine analysis was negative in all respects. Following the operation there was a complete suppression of urine, which occasioned the surgeon much anxiety, and which responded only to most careful and persistent treatment, the patient finally recovering. In this instance had ether been employed it would have been credited with the untoward result.

No one will deny that any anesthetic can cause derangement of the kidney function. Assuming this is so, and it is practically so with ether as with chloroform, as I shall presently show, it is something which can not be avoided. The given patient must be anesthetized; if it is properly done, the danger of kidney derangement, particularly serious, is exceedingly remote.

In the second proposition, on page 734, Dr. Kemp fails to mention the operation itself as a causative factor in renal disturbance. I have noticed this following anesthesia with ether or chloroform, especially in abdominal cases, with excessive manipulations, and I think, had the other anesthetic been employed or none at all, the result would very probably have been the same. The sympathetic system in the splanchnic area has an intimate relation to the kidneys. Excessive manipulation in the abdominal or even pelvic cavity can produce kidney derangement as well as intestinal paresis (even here rarely fatal) without either anesthetic, in my opinion, being at fault.

An interesting case might be mentioned. In the hospital before alluded to a patient was operated upon for appendicitis. Chloroform was employed, the patient having a slight cough which could hardly be due to bronchitis, as an examination of the chest was negative; the urinary analysis was also negative. The operation disclosed a perfectly normal appendix, which was removed, and a very elaborate inversion and suture of the intestine was performed, with part of the patient's intestines exposed and subjected to excessive manipulation. The narcosis lasted nearly two hours. The following day the urine analysis disclosed a small amount of albumin and casts. This condition continued until the eleventh day, when the patient died. The autopsy disclosed congestion about the seat of operation and an emphysematous condition about the tissues in the vicinity of the abdomi-
inal incision. I do not consider the anaesthetic at fault in this case. The same may be said for the following: Recently I administered ether, preceded by nitrous oxide, to a patient whose urinary analysis was negative. The operation of vaginal section was performed and lasted an hour and a quarter. During this time three gallons of gas and, in all, an ounce and a half of ether were used. On the second day after the operation the urine was found almost solid with albumin. The following three days it had almost disappeared. During the operation there was considerable manipulation in removing the sac of an ectopic gestation. Note the small quantity of ether used. At the end of this operation the quantity of urine obtained by catheter was an ounce and a half; specific gravity, 1.015; no albumin. There was also no albumin for twelve hours following operation. This patient recovered with the free use of lithia waters and colonic enemata.

Dr. Kemp does not tell us whether the methods of anesthesia were approximately those used in clinic cases. Evidently not, from the number of times artificial respiration became necessary, which he mentions in his A. C. E. experiments.

Now, the incontestably point which I wish to emphasize in connection with Dr. Kemp's paper is, "invariably," he says, "etherization in dogs produces, first, albumin, second bloody urine, and third suppression"; further he says: "With chloroform, albumin is not produced until near death, and when the circulation is dangerously depressed, also there is an abundant secretion of urine." Now, I will not deny this is the case in dogs, but I certainly do deny, and emphatically, and I will verify my assertion with the most perfect tabulated statistics that any one could desire, that this is so in clinical anesthesia, and I think observers will agree with me that, first, albumin following etherization is rare, considering the vast number of patients anesthetized by this agent, and exceedingly rare when it is properly administered.

Secondly, albumin and suppression do occur with chloroform, though slightly less frequently than with ether, but in my experience it persists longer. In my first observations, in a large series of cases, albumin followed ether in nine per cent., and chloroform in seven per cent.

I am at present and have been for some time past making further clinical observations upon the effects of anesthetics upon the renal secretion, not only with ether and chloroform, but also with nitrous oxide and nitrous oxide and oxygen; the mixed anesthetics I have discarded, and only in rare instances do I use the A. C. E. mixture, having from experience found that I could accomplish with ether or chloroform everything that the most enthusiastic advocates have claimed for these anesthetic mixtures.

In the experiments where chloroform is used, Dr. Kemp says "the fall in pressure is due to the effect of chloroform upon the heart." This is, I think, a mistake, for in prolonged chloroformization the heart is in most cases only affected secondarily as a result of the great fall in blood-pressure due to a paresis of vasomotor tone, particularly in the portal system of vessels, the integrity of which is maintained by the splanchic nerves. It is this depression, frequently termed shock, which often turns the balance against the patient, and just here is where ether's superiority is shown, acting as it does as a stimulant throughout narcosis, and only in case of considerable hemorrhage or with excessive manipulations in the large body cavities does the vasomotor system first, and secondly the heart, become dangerously depressed.

Regarding the A. C. E. experiments, the correct interpretation, I think, is this: Chloroform being the more potent agent, its inhalation is accelerated by ether, a more volatile one; the vasomotor depression more than overbalances the stimulating effects of ether, hence the fall in blood pressure causes the lessened amount of albumin and the greater quantity of urinary secretion. The reason the secretion is not suppressed is the depressed state of the circulatory apparatus. Further on he says that where A. C. E. was freely administered artificial respiration had to be performed on every dog. Is it not a clinical fact that, even when one is using the A. C. E. mixture, artificial respiration is very rarely necessary, an evidence, by the way, that this mixture of anesthetics was not administered as it is clinically? The A. C. E. mixture is extensively used by some anesthetists of great experience, and when I say anesthetists I do so advisedly, for all administrators are certainly not anesthetists.

In reference to the cases cited by Dr. Kemp where the patient's death was traceable to ether, I should like to say that, glancing over the different cases, one is immediately impressed with the fact that they were all practically celiotomies. I presume that in the two cases of fibromyomata uteri also the operation was done through the abdomen.

Without in any way questioning the surgeon's ability in Case 1, other factors could very well have been the cause of the patient's death, such, for instance, as sudden chilling, as mentioned in the beginning of his paper, and shock dependent upon the operation. The same may also be said of the other cases. We are not told in any of these cases the length of time consumed in the operation. Again, I am free to admit that the result may have been due to the anaesthetic, but when we consider the intimate connection between the sympathetics of one part of the abdomen, for instance, the intestines and the kidneys, and in most of these cases more or less manipulation from the nature of the operation occurred, we are justified in assuming that other factors besides the anaesthetic could very well have been at work.

I note Dr. Kemp made no observations regarding deaths from chloroform. Since he made his paper clinical as well as experimental, for purposes of completeness clinical observations of deaths resulting from chloroform should not have been omitted, but possibly, as in most city hospitals chloroform is only given in exceptional cases, it was from the small number of narcoses conducted with this agent that he was unable to do so.

The statement that in ninety-seven cases in which ether was administered albuminuria occurred in 63.8 per cent. seems almost incredible, no matter what the method of anesthesia.

I should like to say that I consider chloroform an ideal anaesthetic and it has a distinct place in surgery. While I always administer it in appropriate cases, yet, from a large experience with this agent and ether, I must emphasize the fact, which I am confident any one will who administers both anaesthetics in a sufficiently large number of cases to become familiar with each, that ether is the safest general anaesthetic known, notwithstanding the remote complications often attributed to it.

S. Ormond Goldan, M. D.
THE ETIOLOGY OF TUBAL GESTATION.

St. Augustine, Fla., December 8, 1899.

To the Editor of the New York Medical Journal:

Sir: An attempt at abortion in the first few weeks of gestation is conducive to tubal trouble. In tubal pregnancy, where previous pelvic disease can be excluded, close questioning will reveal the fact that in a large percentage of cases an effort was made, immediately upon the non-appearance of the menstrual flow and when conception was suspected, to bring on the discharge by the use of some preparation having emmenagogue properties or an expulsive action, with the result of preventing the descent of the fructified ovum and hastening rupture through the action of such remedies on the circular fibre. This knowledge, when obtained, is an etiological factor in the diagnosis.

Edward Jackson, M. D.

A MATTER OF AUTHORSHIP.

Denver, Colo., December 7, 1899.

To the Editor of the New York Medical Journal:

Sir: In Sajous's Annual and Analytical Cyclopedia of Practical Medicine my name has, by mistake, been appended to the article on Diseases of the Lens. This excellent article was written, as I am informed, by Dr. Frank W. Marlow, of Syracuse, and he should have the credit for it.

Edward Jackson, M. D.

Special Articles.

THE LAW IN ITS RELATIONS TO PHYSICIANS

BY ARTHUR N. TAYLOR, LL. B.

L. PRIVILEGED COMMUNICATIONS.

(Continued from page 390.)

The question of privilege has repeatedly arisen in cases where an insurance company has sought to avoid liability upon an insurance policy by showing the assured's physician that at or previous to the time of entering into the contract of insurance he was afflicted with a disease, the existence of which he had denied in his application for insurance.

In an application for insurance it is usually required of one to give the name of his physician for the purpose of verifying the applicant's statements regarding the condition of his health. This reference does not, however, amount to a waiver of the privilege, and will not enable the insurance company to place such physician upon the witness stand and elicit from him the assured's physical condition at the time or times mentioned in the application.*

When, however, the application contains a clause waiving all provisions of the law preventing a physician from disclosing any information acquired in attending the applicant in a professional capacity, the effect will be to completely waive the privilege, not only as to the assured, but also to any one claiming benefit under the contract of insurance.†

The legislature of New York in 1891 amended the law providing for the protection of professional communications so that a physician could not be examined regarding information obtained in the course of his professional intercourse "unless the provisions thereof are expressly waived upon the trial or examination by . . . the patient." This act was held by the court of appeals not to apply to a waiver executed prior to the amendment of the law. And the supreme court has, in two well-considered decisions, held that a waiver executed subsequent to the enactment of the law may be used upon the trial after the patient's death to authorize a disclosure. In the case of Dougherty vs. Metropolitan Life Insurance Company, the court said: "If the patient be alive, an entry upon the record at his trial by his counsel would be sufficient. In case of his inability to attend the trial, a written stipulation signed by him and entered upon the record would remove the prohibition.

"That being so, it must certainly be immaterial when the stipulation is signed. In this case it was signed long before the trial in anticipation of that event, and with design of having it used thereat. . . . The reasonable construction of the statute, therefore, is that the provisions are expressly waived upon the trial if a proper stipulation to that effect be produced thereat and entered upon the record, regardless of the time when the waiver was executed."

With the evident intent of overcoming the effect of this decision and nullifying the waiver contained in the application for an insurance, the legislature of New York, in 1899, amended the statute by adding to it the following words: "The waivers herein provided for must be made in open court, on the trial of the action or proceeding, and a paper executed by a party prior to the trial, providing for such waiver, shall be sufficient as such a waiver. But the attorneys for the respective parties may, prior to the trial, stipulate for such waiver, and the same shall be sufficient therefor." † What the effect of this amendment may be can not be stated until the parties interested in its adoption have devised means to accomplish that end, and those means have been passed upon by the courts.

It has been observed that the privilege does not expire with the life of the patient. The question therefore naturally arises whether or not the privilege may be waived after the patient's death, and, if so, to whom does this right descend?

The New York statute previous to its amendment in 1892 provided that privileged communications should not be disclosed unless the "provisions of the statute were expressly waived by the patient." It was therefore held under this statute that a patient by dying without first waiving his privilege rendered it impossible to remove the seal of secrecy from the lips of his physician. Thus, where one who was insured committed suicide, and his insurance policy contained a clause providing that it should be void if the insured committed suicide, it became vital to the validity of the policy to show that the deceased was insane and either unconscious of the act which he performed, causing his

‡ § 836, Code of Civil Procedure.
* Lodger vs. Whelply, 111 N. Y., 239.
death, or was unable to understand what the physical consequences of it would be. In order to show this the physician who had attended him was called, but upon the evidence being objected to by the insurance company, the court held that under the statute the patient alone could waive the privilege, and, as the patient was dead, the right of granting permission to disclose privileged matter between him and his physician had also ceased, and that the physician could not properly be permitted to make the disclosure asked. That the injustice worked by this law was realized is evident, for the legislature in 1892 amended the statute so as to permit the physician to testify when the privilege was waived by the personal representative of the deceased, or in case of a will contest by the executors, surviving husband or wife, or an heir-at-law, or next of kin, or any other party in interest, except that the physician should not be permitted to disclose confidential communications and such facts as would tend to disgrace the memory of the patient.

The rule enforced by the New York courts previous to the amendment of the statute is followed by the courts of California, where it is held that if the patient dies without having waived the privilege, the matter forever is closed, and the physician will under no circumstances be permitted to disclose the knowledge obtained in rendering professional services to the deceased.† The reason assigned for this strict rule is the similarity of the California statute to that of New York as it formerly existed.

The supreme courts of Michigan, Missouri, and Indiana hold to a contrary doctrine and permit the personal representative of the deceased to waive the privilege, thus qualifying the physician to testify regarding matters otherwise prohibited.‡

In Indiana it is held that in a contest of a will the waiver can be made only by a personal representative of the deceased—viz., an executor or administrator—and if there is no such personal representative the physician cannot be permitted to testify; ‖ but in case of a suit upon an insurance policy the wife of deceased, who is named as beneficiary, is competent to waive the privilege.‡

The rule which seems best calculated to do justice to all parties is that laid down by the supreme court of Missouri in the case of Thompson vs. Ish,⊥ which is that in a will contest any party claiming under the deceased, whether a devisee or heir-at-law, may waive the privilege and call the attending physician to testify regarding deceased’s mental capacity.

(Pit of continued.)

**Pith of Current Literature.**

Vanadium in the Treatment of Tubercle.—The British Medical Journal for December 2d says that attention has been drawn lately to the therapeutic properties of vanadium in anesthesia, chronic rheumatism, diabetes, and neurasthenia. Anceau has just published the results of a series of observations on the use of this drug (Thèse de Paris, 1899), especially in regard to the treatment of tubercle. In this disease vanadium seems to act as a powerful tonic to the appetite and digestive functions. It would seem, however, that the effects of vanadium are only very slight when the pulmonary lesion manifests itself by profound constitutional changes. On the other hand, should the case be one of slight tuberculous affection, especially in the early stages, vanadium seems to be of very great use. The appetite is stimulated in such a manner that the patient is able to take abundance of nourishment, and, what is more important, digestive power is considerably increased. Its method of administration is important. The best method seems to be to exalt the drug from three to five days at a time, allowing a similar interval to elapse before repeating its administration. Vanadium seems to act like arsenic and iron, but appears to be considerably more efficacious in its action than either of these substances, as it seems to have twenty thousand times more oxidizing power than iron, and considerably more than arsenic. The best form is vanadate of sodium, and the writer recommends one thirtieth of a grain (two milligrammes) daily by the mouth, and one six-hundredth of a grain (one tenth of a milligramme) as a subcutaneous injection.

Ouabain.—Gianturco (Rivista medica della regia marina, August; British Medical Journal, October 14th), having had the opportunity of examining a considerable quantity of the roots of Acocanthera ouabaio (the plant from which the Somalis prepare their arrow poison), has made a series of chemical researches on the properties of the alkaloid ouabain. The alkaloid, obtained by precipitation with lead acetate from a watery solution, crystallizes in cubes flattened at the base and of a mother-of-pearl appearance. It is only slightly soluble in cold water, easily soluble in alcohol (at 85°) and in boiling water, insoluble in chloroform, ether, or absolute alcohol. Its elementary composition is represented by the formula $C_{32}H_{43}O_{12}$, with $7H_2O$ of crystallization, which somewhat resembles that of strophanthin. It is one of the glucosides, and when acted on by dilute acids splits up into rhamnose ($C_6H_{14}O_6$) and a resin not yet studied.

**Massage of the Prostate.—M. Aubry (Gazette hebdomadaire de médecine et de chirurgie, September 17th), in a Paris thesis, says that massage of the prostate acts in two ways: Mechanically it empties the glandular ducts of their secretions and exudates, it accelerates the venous circulation and reduces congestion of the organ, and finally it influences the nutrition of the gland by interstitial changes and inducing the resorption of embryonic infiltrations and other morbid deposits. He recommends massage in acute parenchymatous prostatitis, if taken at the beginning, while there is only a simple swelling of the gland, with tenderness. In the final stage of acute prostatitis it further aids resolution; and it is useful at the end of an apparently cured hemorrhapsia, when there often persists the slight mucous, whitish, sterile exudation of "aseptic arthritis." This the author believes to be really due to the congestion of the prostate which accompanies every hemorrhapsia. Massage of the prostate combined with the distinction test by two glasses and aided by
microscopical examination he considers the best means of
diagnosing chronic prostatitis. Massage of the
prostate combined with urethral-vesical irrigations is the
best means of combating chronic urethro-prostatitis, in
which irritation alone often fails.

Toluidine-blue in External Ocual Inflammations.—
Veasey (Virginia Medical Semi-Monthly; Journal of
Eye, Ear, and Throat Diseases, October) describes tolu-
didine-blue as a bluish crystalline powder, soluble in water
and alcohol. The most useful strength is 1 to 1,000.
In all varieties of conjunctivitis and in keratitis he con-
siders it a valuable collyrium. It has the advantage of
deeply staining cornea denuded of its epithelium, so
that the extent of the diseased portion can easily be
seen. In dacryocystitis it is exceedingly valuable.

Face Veil a Cause of Erythema.—O. Rosenbach
(Berliner klinische Woehenschrift, October 9th and
15th) says that a veil drawn tightly compresses the
nose and a portion of each cheek, disturbing the circu-
lation and leading, possibly, to permanent dilatation of
the vessels and consequent disfiguring redness, the area
of which resembles a butterfly in shape, betraying its
mechanical origin. The confined steam from the breath
also adds to the effect, while entering a warm room
directly from the cold outside exaggerates all the evils
of the tight veil.

Heredity in Tuberculosis.—Dr. Flick (Journal of
Tuberculosis, October; Charlotte Medical Journal, No-
vember) says that instead of the son of a tuberculous
father being sure to have the disease, he may have in
his make-up a more than ordinary amount of resistance
to the germs. Instead of inheriting the disease we may
possibly inherit immunity from it. The development of
the contagion theory has done much to prepare our minds
for the reception of immunity ideas in regard to
tuberculosis. So then, says Dr. Flick, instead of sitting
down moping because our fathers had consumption, let
us stir about and assist a possible immunity conferred
on us by that very fact.

Precocious Dentition.—Dr. R. Lynn Heard (Brit-
ish Medical Journal, December 2d) relates the case of
an infant, a girl delivered at seven months and a half.
Labor was induced on account of justo-minor pelvis.
The baby was perfectly normal and healthy in every
way, but had the two lower central incisors appearing
under the gum. These cut through in a few days after
birth, the right on the fourth and the left on the fifth
day, as well as the author recollects. As in Jonokvsky's
case, in a few days an abscess began to form and the
teeth to loosen. Dr. Heard then extracted them, and,
as in the other case, it required a distinct effort to re-
move them. They were typical milk teeth of a bluish-
color. For some time after the lateral incisors appeared
there was a gap, but at the time of writing this had
closed, and no one, unless they were in the secret, would
remark anything amiss. This case is of special interest,
owing to the fact that the teeth were cut at a period of
seven-months-and-a-half gestation.

Intravenous Injection of Antidiphtheritic Serum in
Grave Cases.—Gagnoni (Annales de medecine et chirur-
gie infantiles, August 15, 1899; American Journal of
the Medical Sciences, December) reports three cases of
grave diphtheritic angina complicated with croup and
with symptoms of imminent suffocation occurring in
young children, which, with the advice of Professor
Selavo, of Sienie, he treated by intravenous injections of
antidiphtheritic serum. The results were most satisfac-
tory, the temperature falling to normal, and stenotic
symptoms disappearing with the expulsion of false
membrane.

General Surgical Anesthesia and Anæsthetics.—Dr.
Ernest J. Mellish (Medicine, December) concludes a
paper on this subject with the following propositions:
1. Chloroform almost invariably kills by its effect pri-
marily upon the circulatory system, and ether by its
effect primarily upon the respiratory system. There
probably are exceptions to both of these rules; conse-
quentially hair-splitting discussions on this point are un-
practical and useless. 2. In anaemia of the medulla
the patient should be placed in the head-down position.
In sudden paralytic dilatation of the right heart, as
after several deep inhalations of chloroform, the heart
should be rhythmically compressed by squeezing the
chest; or the patient placed temporarily in the feet-
down posture to empty the heart, artificial respira-
tion being constantly maintained. 3. Anæsthetics act
directly or indirectly upon all the tissues, interfering
profundly with metabolism; and they tend to produce
degenerative changes in the tissues, especially those of
the vital organs. Of the anæsthetics in general use,
chloroform is probably most dangerous in this respect.
4. Deductions based upon laboratory experiments are
apt to be deceptive, and should be accepted with the
greatest caution in regard to sick human beings, unless
they agree with conclusions based upon clinical investi-
gations. 5. As a rule, ether produces less circulatory
depression than chloroform. It causes dilatation of
arterioles and increased capillary circulation, thereby
insuring a good blood supply to the circulatory and
respiratory centres and to the heart muscle; conse-
quently these systems are in less immediate danger with
ether than with chloroform. 6. Cocainizing the nasal
mucous membrane to antidote certain bad effects of
anæsthetics is not a commendable practice. 7. On ac-
count of the reduction of body heat by anæsthetics, they
should be administered in a warm room, and the patient
should be protected from loss of heat so far as prac-
ticable by proper covering of the body, by application
of artificial heat, and by protection from dampness of
the skin. An excessively high room temperature will do
harm by adding heat depression to anæsthetic—and
operation—shock.* 8. Ether, when properly adminis-
tered, is no more liable to produce nephritis than chloro-
form, perhaps not as much so. The changes produced
in the kidneys by ether are as a rule temporary, while
those caused by chloroform are apt to be more per-
sistent. 9. Most of the pronouncedly dangerous effects
of ether, and to a less extent of chloroform, upon the
kidneys are due to poor preparation of the patient,
faulty administration, bad after-treatment, or all of these
combined. 10. Postanæsthetic nausea is best pre-
vented by preparation and after-treatment which favor
normal physiological tonus, with especial reference to
the emunctories. Gastric lavage at the termination of
anæsthesia, followed by vinegar inhalation, will in the
great majority of cases prevent serious disturbance
from nausea. 11. The danger from haemorrhage is no
greater with ether than with chloroform, perhaps not

* The researches of Dr. Robert Coleman Keepp and Dr. W. H.
Thomson, published in our issues for November 18th and 25th and De-
cember 2d, appear to directly controvert this proposition.
so great, since the bleeding which occurs from the effects of ether is primary and is more certainly provided against; while the circulatory depression and the vasomotor constriction due to chloroform to a great extent prevent primary bleeding and lead indirectly to later haemorrhage. 12. The safety margin between sufficient chloroform for anaesthesia and the lethal dose is much narrower than it is with ether. 13. Patients should be well fed with easily digested and nonbulky food to within a few hours preceding anaesthetization, and should be allowed water to within two or three hours of the time. Failure to follow this rule will be likely to make the elimination of the anesthetic more rapid, and less harm is likely to accrue to the emunctory organs. For the same reasons water should be given as liberally as practicable after anaesthesia. 14. Routine methods in selecting anaesthetics should be avoided so far as practicable, the anesthetic being selected according to the conditions present in the individual case. 15. Any anesthetic, but especially ether, should be given with the greatest caution in the presence of special susceptibility to acute bronchial or pulmonary affections. 16. Further clinical investigation in the use of nitrous oxide is desirable and necessary, in order to establish its status in relation to surgery; but its general employment is not practicable. 17. The majority of inhalers on the market are bad. An inhaler made on the principle of the Eschmarch chloroform mask is the cleanest, safest, and best for ether as well as for chloroform. However, the "open method" of administering ether is not practicable in the tropics, at great altitudes, or in open-air military surgery, on account of too rapid diffusion. 18. The ordinary tongue forceps is a barbarous instrument and is often barbarously used. 19. The mouth gag can usually be dispensed with; its use is often positively dangerous, from forcing the base of the tongue against the pharynx. 20. The post of anesthetist is second only in importance to that of the operator, and the selection of an anesthetist should be made with great caution where possible. No person who has not a wholesome fear of anaesthetics can be trusted to administer them. Beware of one who believes any anaesthetic to be "perfectly safe." 21. The anesthetist should gain the complete confidence of the patient as to his ability and carefulness, so that the latter's mind will be at rest on these points. 22. Patients who greatly fear anesthesia are the ones likely to give the most trouble to the anesthetist. 23. Other things being equal, the intelligent and educated take anaesthetics better than those of low intellect. 24. The patient should be kept as free as possible from unnecessary noise and other disturbance during the induction of anesthesia. 25. The pupillary reflexes constitute the best guide to the presence or absence of surgical anaesthesia. 26. The anesthetist should watch carefully the pupils, pulse, respiration, and the color and condition of the skin, depending upon no single symptom as a danger signal. 27. The patient should be carefully watched from the beginning of the anesthesia until fully restored to consciousness. 28. When anaesthetics are properly administered patients seldom struggle. 29. Noisy breathing during anaesthesia should be the exception, as it generally means faulty administration. 30. The minimum amount of anesthetic should be given consistent with the production and maintenance of the desired degree of anesthesia. 31. Compression of the phrenic nerve will, if properly done, usually control retching and kindred symptoms occurring during anesthesia. 32. The use of drugs preceding and during anaesthesia should be avoided save where positively indicated, and if resorted to they should be used with the greatest care. It is best to depend almost wholly upon other means for the prevention of syncope or for resuscitation. 33. Anaesthetic mixtures are in general less safe than the "straight goods." One can not know the relative proportion of the different components that the patient actually inhales. 34. Partial or "talking" anesthesia is advisable in some cases, but should be avoided in delicate or sensitive patients, especially for prolonged operations, since the following anesthetic will be less likely to cause the apparent abolition of pain sense. 35. Finally, the subject of anaesthesia and anaesthetics should be thoroughly treated in medical colleges, and each student required to conduct a number of anaesthesias under the supervision of an expert.

"Lobengulism," or Lipomatosis Universalis Asexu-alis.—Mr. Jonathan Hutchinson (Polyclinic, October), in a recent clinical lecture, said that among the most interesting of the cases which he had had before him were two illustrating the condition which he had described under the name of Lobengulism in volume vi of the Archives of Surgery. The peculiar features of this condition were a general increase of subcutaneous fat, in association with partial or complete abeyance of sex function. In men, the mammary glands enlarged and the sexual appetite failed; and in women, menstruation ceased. The cases referred to were presented on different days, but it would be convenient to describe them together. The male patient was a young man of twenty-eight, of almost gigantic proportions, standing six feet two, and very stout. He was fat everywhere—face, limbs, and trunk; and large seams of atrophy had been produced in various regions by the stretching of the skin. He was quite beardless, and had large mammary glands. Although looking strong, he complained of feeling weak. He had hair on his pubes, but his sexual organs were small and his voice deficient in tone. No opportunity occurred for inquiry as to his sex function, and it is not suggested that it was wholly in abeyance.

In the other case, the patient was a young woman, who, formerly in good health and vigorous, had for two years been failing in strength and becoming fat. Her features were disfigured by the fatness of her cheeks, her voice was harsh, and she had ceased to be able to sing. There had been no menstruation for eighteen months. Enormous linen atriopeche occurred along the borders of her armpits, and on her chest, abdomen, and thighs. Some of these were an inch or more in breadth. Different opinions had been entertained as to whether the malady was myxcedema or not, and treatment for that disease had been adopted. At Mr. Hutchinson's request, Dr. Ord was kind enough to join him in a consultation on the case. He agreed in the opinion Mr. Hutchinson had expressed, that it had nothing in common with myxcedema. They agreed in the diagnosis (nominal) of lipomatosis universalis, to which might perhaps be added the adjective asexu-alis. It might be noted that the influence of the sexual system in connection with the tendency to fatten had for long been matter of observation.

Epidemic Diarrhoea.—Dr. Arthur Newsholme (Lancet, December 2d), in an exhaustive paper recently read before the Incorporated Society of Medical Officers of
Health (England), summarizes the evidence collected by him as follows: "a. It is clear that towns with a high temperature and a deficient rainfall, especially in the third quarter of the year, suffer severely from diarrhoea. This relationship is so close that the towns may be classified meteorologically in the order in which they ought to stand in reference to diarrhoea, and their true relative position as to domestic and municipal sanitation may be ascertained when we know whether they occupy a better or worse position on the list of towns than that which their meteorological place would indicate as right-fully belonging to them. b. It is clear that among populations living on impervious and rocky soils diarrhoea is not so prevalent, probably because polluting fecal and other organic impurities do not cling to, or soak into, such soils. c. Diarrhoea is most prevalent where the systems of removal of sewage and house refuse are the least satisfactory. The exceptionally good position of certain towns in which pail closets are largely used must be regarded as due to the favorable climatic and physiographical position of these towns, probably aided by efficient municipal scavenging; and it is almost certain that their position might be still further improved by the general adoption of a water-closet system."

Dr. Newsholme concluded:

"The fundamental condition favoring epidemic diarrhoea is an unclean soil, the particulate poison from which infects the air and is swallowed, more commonly with food, especially milk. In other words, epidemic diarrhoea is, like enteric fever, a "filth disease." There are, however, certain points of contrast between the two diseases. In the Annual Summary of the Registrar-General for 1898 is a table giving the average death-rates for diarrhoea and enteric fever, 1888-97. The clue to the difference of incidence of the two diseases will, I think—apart from the fact that enteric fever is a disease more particularly of adults, who are in the habit of taking infected foods not eaten by infants—be found in the view that the causation of diarrhoea is most closely associated with surface pollution of the soil, that of enteric fever with less superficial pollution of the subsoil from cesspools and leaky drains, as well as from privy middens. It will be noted that I have hitherto refrained from discussing the influence of artificial feeding of infants with cow's milk in the causation of diarrhoea. Milk is, however, not the actual cause of diarrhoea. It is a vehicle of infection, just as mosquitoes are a vehicle of malaria, or rats of plague; and our ultimate research ought to be directed toward elimination—if it is practicable—of the actual conditions under which the contagia of these diseases are able to live."

Linear Electrolysis in Urethral Stricture.—M. Larroude (Gazette hebdomadaire de médecine et de chirurgie, September 17th), in a Paris thesis, considers that linear electrolysis in urethral stricture and blennorrhoea presents the following advantages: 1. Easy operation, but slightly painful, applicable to all kinds of stricture save very hard ones. 2. Little or no blood exudation. 3. Rarely if ever followed by pyrexia. 4. No need for retained catheter. 5. The possibility of urinating immediately in a full stream. 6. The possibility of the patient in almost every case resuming his occupation the next day. 7. Further, according to the author, linear electrolysis in blennorrhoea produces a marked amelioration, is without any risk, and deserves such thorough trial that its real value may be established.

Pelvic Peritonitis in the Male.—Doyen (Revue de chirurgie, November 10th) says that pelvic peritonitis in the male, which has not been sufficiently studied, is produced in many ways. In certain cases it comes from below upward, taking its origin from the prostate or vesiculæ seminales, in perforations of the rectum, in abscesses of the anterior surface of the sacrum, or even from hydatid cysts in the pelvis. At other times it takes a descending course, and its commonest origin is then appendicular. In two cases of tuberculosis of the prostate, M. Doyen freely incised the perineum, opened the rectum by two valvular incisions, and removed the prostate and the vesiculæ seminales.

---

Book Notices.

These two volumes are devoted to certain of the infectious diseases. The first section in volume xvi is that on lobar pneumonia, by Dr. A. H. Smith, who defines the disease as one in which "a specific parasite invades the air cells of one or more pulmonary lobes, where it grows in a fibrous medium exuded from the functional capillaries, and generates a toxin that infects the system at large," so that the author believes all cases of this disease are caused by pneumococcus infection. The clinical symptoms, etiology, pathology, diagnosis, and treatment are described in considerable detail.

Dr. A. Netter has written the section on cerebrospinal meningitis. He regards the Streptococcus meningitis capusatus of Bonomé as a form of the pneumococcus, and he deems it possible that Weichselbaum's Diplococcus intracellularis meningitis is a degenerated form of the pneumococcus. While infection may reach the meninges by way of the nasal fossa, he thinks it usually occurs through the pulmonary alveoli. The etiology, pathology, diagnosis, treatment, and epidemiology are described at length.

The paper on dysentery is by Dr. A. A. De Azevedo Soáré, who considers it an "infecto-contagious disease, endemic in warm countries, sporadic or epidemic in temperate regions." The author's efforts to prove the contagiousness of the disease do not convince. He considers the theory of the amoebic etiology of the disease as the most likely, but believes that serial conveyance of the dysenteric germ is beyond dispute. He deems the specific treatment one of the most satisfactory. There is not much said about the advantages of high enemata for lavage of the colon.

Dr. H. A. Alford Nichols describes yaws in a brief, well-written paper that gives a very satisfactory account of the disease.

Professor Ernst Ziegler has written the chapter on inflammation, which constitutes a most able presentation of the present state of our knowledge of this process.

Dr. Otto G. T. Kiliani is the author of the chapter on erysipelas, and he has reviewed carefully the various features of that disease.

Simple continued fever is described by Dr. Landon..."
B. Edwards, who very properly considers it a symptomatic fever due to hermic or nervous causes.

Dr. Leo Popoff has written the paper on relapsing fever, in which the facts of that disease are carefully reviewed.

Dr. John S. Thacher is the author of the section on the aetiologie and general pathology of typhoid fever, and those subjects are described with a thoroughness of detail that makes this a most valuable chapter.

Dr. John Winters Brannan, in his article on the symptomatology and treatment of typhoid fever, shows a wide knowledge of the literature of this disease, and displays a skilful analysis of his clinical experience.

The first article in the seventeenth volume is on the general pathology and bacteriology of diphtheria, and is by Dr. W. H. Park, whose name is sufficient authority for the thoroughness with which these subjects are treated. Dr. A. Jacoby is the author of the section on the symptomatology and treatment of diphtheria.

Professor Victor Babes contributes the section on tetanus, and he displays a very conservative view in regard to the treatment of the disease with antitoxine, which he thinks should be given so as "to inundate the organism continuously or very frequently with large quantities," his doses being from three hundred to five hundred cubic centimetres. While he regards this treatment as a marked advance, he thinks it should not restrain us from making use of other well-tried remedies.

The general pathology of cancer is described by Mr. W. Roger Williams. He dismisses the theory of the agency of microbes as no more necessary to account for the genesis of cancer than it is to account for the genesis of a tooth or a hair. While he does not think the disease can be transmitted from one person to another, he considers the disease inoculable, and he presents evidence to show the possibility of benign neoplasms taking on malignant characters. The author's views are well presented and he substantiates his positions by adding well-considered evidence.

Dr. W. B. Coley is the author of the section on the symptomatology and treatment of cancer.

Mr. W. Roger Williams has contributed an excellent paper on the general pathology of sarcoma, and Dr. W. B. Coley has described the symptomatology and treatment of that form of neoplasm. He gives in detail the method of treatment with mixed toxins.

Dr. J. T. Bowen is the author of a section on malignant new growths of the skin, and Dr. Edward McGuire has described briefly the malignant diseases of the organs of generation in women.

within a period of possibly ten years the surgical treatment of ureteral injuries has undergone a great change. A number of causes have contributed to produce this change. Among them may be mentioned the greater frequency of injuries during abdominal operations, especially those by the vaginal route, and, secondly, the increased confidence of the profession in its ability to operate under conditions of shock which would have been regarded as a contra-indication to surgical interference a decade ago, and also to the confidence based on the experience that it is possible technically to suture the ureter and obtain primary healing. For these reasons chiefly there has grown up a considerable amount of surgical knowledge, partly based on animal experimentation and partly the result of bitter experience in repairing the damage done to the ureter during the course of an operation. The author of this small monograph has been one of the original investigators in this field and has endeavored to fairly cover the subject of ureteral anastomoses with some success.

The operation of uniting the severed ends of a ureter has been accomplished some fourteen times, with fair results, and the method of remedying vesical extravasation by implantation of the ureters in the rectum has a recognized position as a surgical measure which can now be carried out with some degree of safety. The volume gives a good historical survey of the whole subject.

**The Abdominal Brain and Automatic Visceral Ganglia.**

This volume is an attempt to unite the scattered anatomical and physiological knowledge of the sympathetic system and to combine the whole so as to render that knowledge accessible and useful.

Interwoven with this information is a large amount of practical medical application of the facts in a manner to be extremely useful. The only criticism to be made is that the drawings are not so clear or so well printed as they might be.

**Tesis para el Doctorado en la Facultad de Medicina.**

In this thesis the author has collected from literature an excellent survey of the subject of hysterectomy for fibromyomata of the uterus, and adds to it one case observed personally in which there was nothing especially novel in either the operative method or the result.

**Vital Science Based upon Life’s Great Law. The Analogue of Gravitation.**

The author of this attractively bound book has discovered what he calls "life's great law," and during the exposition of this hitherto unknown "law" finds that he can also furnish "a new theory of creation," "a new theory of the constitution of Nature and man," "a new theory of vital force," and "a new proof of the immortality of man," also a number of subordinate truths, among which may be mentioned the "convincing proof that the paradoxes of Scripture and the Golden Rule are scientific and practical truths." We are sorry that the author should not have been more gentle in his refutation of the idea that Mr. Herbert Spencer knows anything about evolution.

New Inventions, etc.

A NEW ASEPTIC EAR SPEICULUM.

By Henry W. Wandless, M. D.,
NEW YORK.

So complete and beautiful is the cut of this specu-
num that it seems to me little is left to be added regard-
ing its mechanism. The lock consists of a peg and hole
on the lower side and a peg and slit on the upper side.
The lower peg is put in first; then, with the blades
opened almost to their full extent, the upper peg is
slid into the slit. The blades are held firmly and will
not fall apart, yet are easily taken apart for cleansing
purposes.

There are two essential advantages of this speculum,
besides a number of minor ones. First, its easy and
convenient manipulation in the ear; and second, it is
easily cleansed.

It is as nearly self-retaining as any that I know of.
It is picked up by the little handle and placed in
the external canal; then with the left hand it is ma-
nuvered with the greatest ease, the blades being opened
and closed as occasion demands with the tips of the
fingers, using only such force as is necessary. Most
specula, except the cones, are opened and closed by
means of a screw, and one never knows the exact
amount of pressure brought to bear upon an inflamed
canal until the patient cries out with pain.

If hairs get in the line of vision, it can be rotated
instantly, which carries the hair under the blades.

It is readily cleansed of the discharges which often
obstruct the canal. Beyond doubt, this speculum has
more advantages and fewer disadvantages than any
other that I have ever seen. It is made by George Tie-
mann & Co.

45 West Thirty-second Street.

Miscellany.

Dysphrenia.—At a meeting of the New York Neuro-
logical Society, held on December 5th, Dr. William
Hirsch read a paper with this title. He said that the
term dysphrenia had been applied to the secondary, or
sympathetic, psychoses in contradistinction to the idio-
pathic, or mental, diseases, such as mania and melan-
cholia. The secondary psychoses, which were produced
by bodily diseases, he said, were not characterized by
the same uniformity of symptoms that marked the idio-
pathic variety. In the secondary psychoses there were
frequent remissions with perfect lucidity during the
course of the disease. Outbreaks of violence might be
quickly followed by stupor. The speaker said that a
further characteristic which he would call attention to
was the occurrence of somatic symptoms, such as loss
of pupillary or patellar reflexes, rise of temperature, irreg-
ularity of the heart’s action, and certain vasomotor phe-
nomena, such as oedema. In the secondary psychoses,
the interstitial tissues, and particularly the blood-ves-
sels, were the ones at first and mainly affected. This
was in accord with the accepted pathology of the
systemic spinal diseases. The changes in the intersti-
tial tissues were produced by the diseases starting out-
side of the brain, such as the acute febrile diseases.
There were a few cases in which, purely from the men-
tal symptoms, one was justified in making a diagnosis of dysphrenia, even though ignorant of the exact nature of the underlying bodily disease. A case of this kind was then reported by Dr. Hirsch. The patient was a young and neurotic girl, seen by him first on September 3, 1896. She had then presented the condition of hallucinatory confusion. After an interval of quiet, on February 17, 1897, she became violent and had hallucinations of hearing and sight. At this time the temperature was normal. After about ten days she became stupid; her pupils were contracted, and the pulse was small. After about three days automatic movements of the hands and head appeared. On March 14th menstruation came on, and she quickly became normal, and remained well for ten days. In April, 1897, she was given thyroid extract, and quickly recovered. She remained well for nearly two years. On February 2, 1899, she was suddenly seized with the same violent symptoms as before. She showed some transitory improvement again under the administration of thyroid extract, but soon passed into a condition of dementia. After about three months she became quieter; the pupils and pupillary reflexes returned, the temperature became normal, and her breasts, which had been much enlarged, returned to their natural size. Since that time her mental state had been good. The clinical features of this case evidently did not correspond to any primary psychosis. A loss of reflexes was generally considered as indicative of permanent change, but it was not impossible that this symptom might exist in functional disturbance. In the case reported he believed that the menstrual disturbances were not the cause, but a symptom, of the disease, as in the fourth, or worst attack, menstruation had had little or no effect on the mental state. The speaker suggested that the term “originary dysphrenia” should be applied to cases which, in their clinical aspects, resembled those known to be produced by toxic or infectious agents, but in which no cause for such infection could be found.

Dr. B. Sachs said that probably everybody present had seen cases similar to the one described. He had himself had under observation a number of women between the ages of fifteen and twenty who had passed through very remarkable periodical mental changes. He had been much impressed with the suddenness with which these changes had occurred. All these patients had been members of highly neuropathic families. They had passed quickly from a condition of mania to one of depression. A patient now under his care had regularly had periods of six months or more in which she had been in a condition of maniacal excitement, and then very suddenly passed into a condition apparently normal, but really only a stepping stone to a period of excitement. It was questionable, in his mind, whether the class of cases spoken of in the paper represented a distinct entity in mental diseases. Such marked physical changes as had been described in the paper had not come under his observation. The President (Dr. Frederick Peterson) expressed his belief that dysphrenia would be a convenient term for cases that it would be difficult to describe under other names. The trouble was that these terms in psychopathy were usually founded upon clinical symptoms, with but little reference to the pathology, so that after a time the word came almost to include all insanity. Last summer, at Heidelberg, he had found about four varieties of insanity recognized—viz., paresis, senile dementia, catatonia, and dementia praecox. About fifty per cent. of the cases in Germany at the present time were called catatonia, and the remainder were included under the term dementia praecox.

Chancre of the Eyelid.—At a recent meeting of the Section in Ophthalmology of the College of Physicians of Philadelphia, Dr. W. F. Norris related the case of a man, forty-five years old, who had presented himself at the dispensary of the hospital of the University of Pennsylvania on October 26th and stated that the disease had started two days before as a little white blister about a quarter of an inch from the external canthus of his right eye. There was marked swelling of the lids, with an indurated lump in the margin of the lower lid near the external canthus, about a third of an inch in diameter and yellowish. The bulbar conjunctiva was highly chemosed and there was a slight conjunctival secretion. The patient had severe nocturnal pain in the forehead and temple. There were no posterior synechiae or other evidences of inflammation of the iris. He was ordered a solution of atropine and ten grains of potassium iodide, the dose to be increased two grains daily. Four days later the face, the lids, and the glands of the neck were much indurated and swollen; the yellow lump on the lower lid had broken down, leaving an irregular open sore and ectropion of the lower lid. The severe symptoms gradually subsided, and on the 27th there was no pain, and the swelling of the lids and the chemosis had decreased. The upper margin of the cornea was the seat of several small superficial ulcers. Holocaine was applied to the ulcers, and the sore on the lid was touched with five-per-cent. solution of protargol, later with mercuric bichloride 1 to 500. On November 1st there was an indurated sore with a sharp-cut excavation. The patient had progressed steadily, and at the time of the meeting, November 21st, the inflammation had subsided, the ulcer was nearly filled, and there were three minute elevations on the margin of the lid just beyond the outer edge of the ulcer. There was no history of infection to be obtained, no lesion or scar on the penis, and there were no symptoms of secondary or tertiary syphilis. The patient attributed the lesion to traumaism, and said that some days before the symptoms appeared the lid was penetrated by a splinter of glass that was removed by a fellow-workman.

The New York Academy of Medicine.—At the last stated meeting, on Thursday evening, the 21st inst., Dr. Richard van Santvoord read a paper entitled The Clinical Uses of the Sphygmograph.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 27th inst., the following papers will be read: The Use of the Supra-renal Extract in Diseases of the Nose, by Dr. W. H. Bates; and Diabetic Ulcers of the Throat, by Dr. W. Freundenthal. The discussion on Dr. Beamam Douglass’s paper, A Study of the Application of the Galvanoeautopsy in the Nose, will be continued, cases will be presented, and specimens and new instruments will be exhibited.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, the 28th inst., Dr. G. Peckham Murray will read a paper entitled A Second Contribution to the Study of Ulcerative Lesions of the Uvula (?), commonly called Lupus or Esthionè. Dr. A. H. Gooch and Dr. H. J. Garrigues will present patients and exhibit specimens and new instruments.

The Late Dr. Samuel Ketch.—Immediately after the stated meeting of the Orthopedic Section of the New
MISCELLANY.

York Academy of Medicine, held on December 15, 1899, had been called to order, it was, on motion, adjourned out of respect to the memory of Dr. Samuel Ketch, and a committee was appointed by the chair to express the sentiments of the section.

The committee reported as follows:

The Orthopedic Section of the New York Academy of Medicine desires to express its profound grief at the sudden death of Dr. Samuel Ketch, one of its most useful and honored members.

An original member of the Orthopedic Society, since merged in the Orthopedic Section of the academy, he served as its secretary in 1889 and as its chairman in 1891, presented several valuable original contributions, and was at all times prominent in everything pertaining to its best interests and progress.

Identified with the practice of orthopedic surgery for nearly twenty-five years, and in every way devoted to the advancement of his chosen work, his life was one of consistent uprightness and honest and successful effort.

The District of Columbia Antivivisection Bill.—We take pleasure in publishing the following appeal to the members of the medical profession in the United States:

The cause of humanity and of scientific progress is seriously menaced. Senator Gallinger has again introduced into congress the bill for the further prevention of cruelty to animals in the District of Columbia, which he has so strenuously and misguidedly advocated in the last two congresses. Its present number is "Senate Bill No. 34." Twice the committee on the District of Columbia has also unfortunately and misguidedly reported the bill with a favorable consideration. The bill is specifically drawn to seem as if it were intended only in the interest of prevention of cruelty to animals. The real object of the bill is twofold: First, to prohibit vivisection; and, secondly, to aid the passage of similar bills in all the state legislatures.

I need hardly point out to you that this would seriously interfere with or even absolutely stop the experimental work of the Bureau of Animal Industry and the three medical departments of the government—the army, the navy, and the Marine-Hospital Service. The animals themselves might well cry out to be saved from their friends. No more humane work can be done than to discover the means of the prevention of diseases which have ravaged our flocks and herds. All those who raise or own animals, such as horses, cattle, sheep, pigs, chickens, etc., are vitally interested in the preservation of their health and the prevention of disease.

The inestimable value of these scientific researches as to the prevention and cure of disease among human beings it is superfluous for me to point out. Modern surgery and the antitoxine treatment of diphtheria alone would justify all the vivisection ever done.

As my attention has been called officially to the introduction of the bill, I take the opportunity of appealing to the entire profession of the country to exert themselves to the utmost to defeat this most cruel and inhuman effort to promote human and animal misery and death, and to restrict scientific research. It is of the utmost importance that every physician who shall read this appeal shall immediately communicate especially with the senators from his State, and shall also invoke the aid of the representatives from his or other districts in his State, and by vigorous personal efforts shall aid in defeating the bill.

It is especially requested also that all the national, State, and county societies at their next meeting take action looking toward the same end. If regular meetings are not soon to be held, special meetings should be called. Correspondence is invited from all those who can give any aid.

[Signed.]

W. W. Keen,
President of the American Medical Association.

The Medical Society of the State of New York.—Owing to the illness of the secretary, the announcement of the business committee has been unavoidably delayed. Dr. Wendell C. Phillips, of No. 330 Madison Avenue, New York (chairman), Dr. Henry L. Elnner, of Syracuse, and Dr. Chauncey P. Biggs, of Ithaca, are the members of the committee. We learn that the preliminary programme will be published about January 1st.

A Physiological Interpretation of the Couvade.—In our issue for July 8th we described the Curious Custom of the Couvade. M. Charles Féré (Société de biologie; Revue médicale) refers to this subject apropos of the curious phenomenon of the intractable vomiting of a man during his wife's pregnancy. Féré agrees with Weir Mitchell in considering these phenomena to be imitative. The subject in question presented at the time of his wife's accouchement violent lumbar and spinal pains, a condition of acute anxiety, with hyperesthesia of the skin of the abdomen and breasts. On the occasion of a second pregnancy he presented similar phenomena actually realized what is symbolized in the "couvade." The explanation is to be sought in imitation and sympathy—suggestion, in fact—in one predisposed.

White Swelling.—At a meeting of the Section in Orthopedic Surgery of the New York Academy of Medicine held on October 20th the chairman, Dr. A. B. Judson, read a paper on The Pathology and Treatment of White Swelling of the Knee. He said that with the scientific progress of the day great changes were taking place in our knowledge of disease. Although pathology took the precedence in medical studies, she was a fickle divinity. We learned, but with the prospect of having to unlern, and the all-wise, unwise public perceived this, and, when in dire straits, went doubly away, "trembling, hoping, lingering, flying," to fanes where the divinities were not only fickle but meretricious. In white swelling of the knee, however, it was sufficiently established that use of the inflamed joint aggravated and prolonged the disease. Arrest of motion and cessation of weight-bearing necessarily followed as a part of rational treatment. He described apparatus and presented several patients.

Judge-made Law.—The Journal of the American Medical Association for December 2d says editorially that, according to an item in the daily press, a Missouri
The judge has recently decided that any physician who believes the case of a patient to be a hopeless one and fails to so inform him is guilty of a breach of trust. This is a decision that cuts both ways. It may be wrong under certain circumstances to encourage false hopes, but who, asks the Journal, has endowed us with prophetic powers, and what experienced physician has not seen what seemed to be hopeless cases recover? Again, how often do we not know that the abandonment of hope on the part of the patient means a quick succumbing to the disease, when otherwise life is at least prolonged, even in hopeless cases! In such a case the course indicated by this decision would simply mean murder, and if it ever compelled any one to act in accord with it, the judge would be responsible. If physicians claimed to be infallible, the case would be different, and the decision might be a little more rational, but even then it would deprive them of the use of a most important therapeutic resource, the patient's courage and hope, and would therefore be criminal; but as things are it is both criminal and idiotic—a blunder and a crime.

The Yale Medical Alumni Association Lecture was given in New Haven on December 13th by Dr. William P. Northrup, of New York, on Some Paths of Tuberculous Infection.

The Economic and Religious Use of Cow Dung in India and its Bearing on Plague.—We elp the following from an editorial in the Indian Medical Record for October 25th:

"As charity is said to cover a multitude of sins, so religion offers a cloak to many curious superstitions, and often revolting, customs; among the latter may be classed many of the uses to which the various products of the cow are put by the followers of the Hindu faith."

"According to the Bombay Gazetteer, the mantra or sacred verse recited on the Sravani Day, when the products of the cow are exhibited, may be translated thus: 'By the drinking of the five products of the cow, the sin which has penetrated into my skin and bones is burned like fuel by fire.' In fact, the filthy concoctions of the pharmacopeia of the middle ages are equal, if not surpassed, by the ignorant Hindu of the present day, whose blind faith attributes medicinal virtues to the evacuations of his sacred animals.

"The economic importance of cow dung in India can hardly be realized by any one who has not a personal acquaintance with the country. It appears to be essential to the existence of the lower classes. The native lives surrounded by it, he plasters the floor and walls of his house with it, he sprinkles it about his cottage, he uses it to freshen the atmosphere of the house.

"The Latest Therapeutic Fad.—According to the Gazette médicale de Paris for August 19th, the latest discovery exploited among a special group of physicians and destined to revolutionize the therapeutic art is lipiderotherapy, or the treatment of diseases by precious stones. We are not told how the gems are applied."

A Case of Sarcoma of the Stomach in a Child aged Three Years and a Half is recorded in the British Medical Journal for December 2d by Dr. James Finlayson, consulting physician to the Royal Hospital for Sick Children, Glasgow. This would appear to be the youngest subject of sarcoma of the stomach on record.

A State Institute of Serum Therapy, Vaccination, and Bacteriology, to bear the name of Alfonso XIII, has, we learn from the British Medical Journal for December 2d, been created in Madrid by a royal decree dated October 28th. The new institute is organized on the lines of the Institut Pasteur.
Original Communications.

TUBERCLE GERMS AND GIANT CELLS IN HUMAN TISSUE.

[From the Pathological Laboratory of the University of Michigan.]

By PHILIP DAGGETT BOURLAND, B.S., M.D.,
ASSISTANT IN THE CLINIC OF INTERNAL MEDICINE, UNIVERSITY OF MICHIGAN.

An examination of the literature reveals the fact that opinion is not unanimous on the relation between tubercle bacilli and giant cells. Not only do statements vary concerning this relationship in human tissue alone, but the assertion has been made that the giant cells of human tubercle rarely contain bacilli, while those of spontaneous or inoculated tuberculosis of the lower animals commonly inclose them.

Mention is therefore permitted of my own experience in the examination of numerous specimens of tuberculous tissue taken from various parts of the human body, and also reference to some of the more important communications on the subject.

Koch makes the giant cells of tubercle subjects of considerable importance. In his paper on The Etiology of Tuberculosis he devotes considerable space to them and their relation to tubercle bacilli. One of his statements are especially striking and are here quoted. "The conclusion that the infective agent must be contained in the giant cells has been proved correct, for, as soon as giant cells appear in a tubercle, we find, almost always, tubercle bacilli in them." Koch discusses at some length the conditions governing the number of bacilli in a giant cell, and the favorite seats of the former within their host. He pictures germ-containing giant cells from the human lung and mentions the occurrence of bacilli in a majority of such cells in certain cases of tuberculosis of the human liver and spleen.

Slowly progressive processes, such as tuberculous lymphadenitis, joint inflammations, and the like, are characterized, according to him, by very few tubercle bacilli, and the occurrence of these almost exclusively in the giant cells. Usually, however, only one germ, or at most a few, are inside of a cell. In more intense processes the germ are more abundant and one giant cell may inclose fifty or more.

Weigert substantiates Koch's statements as follows: "The remarkably frequent occurrence of bacilli in the giant cells must be touched upon. It is very striking, and Koch was right in saying that every tuberculous giant cell contained or had contained a germ. The bacilli not only occur in these cells, but they have favorite seats within them. They occupy, by choice, the periphery of the portion free from nuclei, and also the border of the nuclear part. Sometimes they lie between the nuclei, etc." It is not evident whether Weigert refers to human tissue, but it may be assumed that all kinds of sources were drawn upon for his material.

The statements of Orthmann prepare one for an occasional disappointment in the search for germ-inclosing giant cells. In the granulations from a tuberculous breast he failed to demonstrate tubercle bacilli in spite of the presence of numerous giant cells. Sections from neighboring lymph glands, however, furnished some giant cells containing each not more than one bacillus. Tissue from a second breast case contained many giant cells, most of which inclosed from one to three bacilli, while a few contained from five to eight.

Fütterer and Krückmann lead one to an opinion different from that expressed in the foregoing quotations. The former, in reporting the microscopic findings in cases of caseous broncho-pneumonia, miliary tuberculosis of the lungs, of the liver, and of the kidney, states that, while many of his sections showed bacilli and numerous giant cells, in no case were the former within the latter. Krückmann makes no mention of the inclosure of bacilli by giant cells in his descriptions of many cases of tuberculosis, among them both lung and joint cases.

It would be hard to draw a definite conclusion from the matter thus far presented, and the following statements from works on general pathology do not offer much help. Payne, for instance, speaks as follows: "One peculiarity should be mentioned as to giant cells which constitutes a difference between human tuberculosis and that of some animals. In specimens from the human subject the giant cells very rarely contain bacilli. The writer has never seen them in that situation, and observers of much larger experience have confirmed this negative result. On the other hand, in inoculated tubercle and the spontaneous disease of some animals—for example, of cattle, poultry, and horses—bacilli are very common in giant cells. No satisfactory explanation has yet been given of this difference."

Coyné, after stating that the bacillus of Koch occupies, as a rule, the centre of the giant cell "in a more or less considerable number," notes a difference between the giant cells of man and those of the lower animals as regards their phagocytic properties, in the following words: "One does not find in man all the transformations of the bacillus in the giant cell; one sees only that the bacilli are dead and stain poorly, etc."

The statements of some other authors, however, admit of no question. Schmaus remarks that in the interior of the tubercle and in the giant cells tubercle bacilli are constantly present, even if it is impossible to demonstrate them microscopically, as is often the case in old tubercles. Orth speaks in the same strain, to the effect that the tubercle bacilli, which are found especially in the giant cells, are necessary and integral
parts of the tubercle, etc. Stengel expresses his views as follows: "The giant cells in particular may contain large numbers of bacilli. As the necrotic changes increase, the bacilli become less and less conspicuous, and eventually none may be visible. The existence of the bacilli or their spores, however, can not be doubted, as portions of such tubercles cause disease in guinea-pigs when injected."

Hamilton says that in the horse the giant cells frequently absorb bacilli in large numbers, while Ziegler contents himself with the assertion that giant cells often enclose bacilli.

My own experience is confined to human tissues. I have kept no record of the number of giant cells examined, but can say that it is in the thousands. The material used included lung, liver, kidney, and spleen tissue, also lymph glands, and in one case granulations from a tuberculous knee. Three cases were drawn upon for the tissue—one of chronic ulcerative phthisis, one of acute miliary tuberculosis, and the knee case already mentioned. In only four instances did I find tubercle bacilli within giant cells. Three of these examples of germ inclosure occurred in lung tissue and the fourth in the liver. The chronic ulcerative case furnished one lung specimen and also that from the liver. The other two examples were from the acute miliary case. Tubercle bacilli could not be demonstrated in the knee granulations, though these were unusually rich in giant cells.

The microscopical findings are as follows:

**Acute Miliary Tuberculosis.**—I. Small tubercle whose centre shows beginning caseation, although the reticulum is still faintly visible. There is but one giant cell in the tubercle; it lies at the edge of the slightly cased part, is of medium size, and has a faintly reticulated protoplasm and numerous nuclei which stain well and are gathered at one pole. The bacilli are two in number; they stain distinctly; one lies just below the row of nuclei and the other at the opposite pole.

In the tubercle, outside the giant cells, germs are absent from the central partially cased portion at the edge of which the giant cell lies. About the periphery, however, in the transition zone between the centre and the part showing merely slight chromatin diffusion, germs are found in small numbers. But five giant cells are present in this section.

II. Large, oval, reticulated tubercle with practically no caseation. It contains one giant cell, which lies near one end in the median line. The giant cell is large and finely reticulated; nuclei are numerous and occupy half of the periphery. One tubercle bacillus is inclosed in the cell; it lies just beneath the nuclei and stains deeply. But one germ is to be seen in that part of the tubercle which immediately surrounds the giant cell, and the rest of the tubercle is quite germ-free. The section contains six giant cells.

**Chronic Ulcerative Phthisis.** Lung section: Small cased tubercle; the centre takes a diffuse faint stain; reticulum very faint; cells with deep-staining nuclei about the periphery. The tubercle contains two giant cells about midway between the centre and the edge. One giant cell contains two bacilli; the cell is small and cased in the centre; the nuclei almost completely surround the cell. The germs stain faintly and are beaded; one lies in the middle of the cased centre, the other just within the nuclear ring. As in the preceding cases, germs are absent from the cased part of the tubercle and present in the transition zone of beginning necrosis which circumscribes the centre.

Liver section: Small tubercle with incipient casation in the centre; contains three giant cells—one of fair size and cased, the others small. These are situated about equidistant from each other and about midway between the centre and periphery of the tubercle. The large giant cell contains one bacillus, lying close to the nuclei, which occupy half the periphery of the cell. The bacillus stains poorly. The section contains no other tubercle germs, notwithstanding the presence of numerous tubercles and thirty giant cells. Examination of sections from other parts of the same organ gave results wholly negative, although they also showed tubercles and giant cells in abundance.

The granulation tissue from the knee joint is made up mainly of giant-cell tubercles. There is no casation except in the giant cells themselves. Numerous serial sections fail to show any bacilli, nor any found in sections from other parts of the block. This result is especially interesting in view of the statements of Koch, quoted at the beginning of this paper.

In considering the question of difference between giant cells of human tissue and that of the lower animals the literature is of little service. The question is one which evidently has occurred to few investigators. The statements found, with the exceptions noted, make no discriminations depending on the source of the material and lead one to assume that the latter is a factor of no consequence. It is not my purpose to discuss the factors governing the presence of tubercle bacilli in giant cells nor to attempt to explain the discrepancies between the many statements made in that connection. That germ inclosure occurs in the giant cell of human tissue there can be no doubt, but the opinion evidently is justified that the relation between bacilli and giant cells is a variable one and not fixed by anything apparent in the light of our present knowledge.

The question of technical skill may be raised in considering the value of statements on a subject of this nature. I have always used warm, freshly prepared carbol-fuchsin, and stained at least fifteen minutes, that time having been found ample by experiment. My sections were invariably in paraffin and cut at ten microns. The following method of Schmorl's has
proven most satisfactory, and by its use one can, I believe, be more sure of staining all the bacilli in a section than by the methods in which the section is fixed to the cover slip before staining:

1. The sections cut in paraffin at five or ten microns are floated on freshly prepared, warm carbol-fuchsine, which should be heated to just below the melting point of the paraffin.
2. Stain fifteen minutes, keeping stain warm.
3. Wash in water.
4. Decolorize in ten-per-cent. nitric acid.
5. Wash in two changes of water.
6. Transfer to Loeffler's methylene blue.
7. Wash in water.
8. Pick section up on end of slide and orient it.
9. Dry with blotting paper.
10. Hold high above flame to complete drying.
11. Pass through flame to melt paraffin.
12. Plunge into xylol and leave till cleared.
13. Drain off xylol and mount in balsam.

The section may be conveniently handled on a cover slip held in forceps, or on the end of a slide.

A much shorter time is sufficient for staining than is usually allowed. Fifteen minutes I regard as ample to insure safe results, but I have made very satisfactory preparations by staining only three minutes. The whole process of cutting, staining, and mounting may be accomplished in ten minutes.

**The Seventh International Otological Congress.**—According to the Glasgow Medical Journal for December, it has been decided that, owing to the date of the International Medical Congress falling in 1903, the next International Otological Congress shall take place, not in that year, but in 1902. The meeting will be held at Bordeaux, under the presidency of Dr. Moure.

**AN ARRANGEMENT OF GASTRIC INSTRUMENTS DEIGNED TO FACILITATE THE PHYSICAL EXAMINATION OF THE STOMACH AND ITS TREATMENT.**

By CHARLES S. FISCHER, P.D., M.D.

There have been many methods and instruments recommended for the determination of the size, location, capacity, and motility of the stomach. For ordinary clinical purposes that method can be accepted as the best which furnishes us the completest data in the shortest possible time, with the least inconvenience to the patient. It has been my experience that in order to obtain the exact physical condition of the stomach, it is not safe to rely upon any one method, and cases constantly present themselves which are difficult of examination and obscure at best. The temperament of the patient and his physical proportions on the one hand, and the time and experience of the examiner on the other, often stand in the way of a successful diagnosis.

In view of these facts, I have endeavored to construct an instrument which would in some way tend to alleviate the difficulty of examination and render it possible to combine at one sitting the various methods, in the hope of arriving at some satisfactory conclusion in a short space of time and with the least inconvenience to patient and examiner.

It is in the matter of construction and application of its component parts that the novelty of the instrument lies, not in any originality of principle, for the intragastric light, electrode, and douche are well known. Their successful application, however, has often failed, and thereby brought them into disrepute, purely on account of the difficulty of manipulation and the time required to accomplish the desired effect.

The instrument proposed consists of an outer or primary tube and four smaller or secondary tubes. The primary tube (A) is an ordinary lavage tube of very soft and flexible rubber, twenty-eight inches in length and three eighths of an inch in diameter. The gastric end of this tube is open and possesses the usual eye, the edges of both being well beveled. To the external end of the tube is attached a hard-rubber double stopcock. The larger stopcock (B), the diameter of which corresponds to the diameter of the tube, serves the purpose
of admitting fluids by attaching to it the ordinary funnel and suction tube used in lavage. The smaller stopcock (C), placed at right angles to the larger one, is used for the inflation of the stomach by attaching to it a soft-rubber double bulb. The arrangement of both stopcocks is such that when one is closed the other is open.

The smaller or secondary tubes (D), to which are attached the intragastric light, electrode, and douche, are so constructed that they may be passed through the larger opening (B) of the primary tube without necessitating its removal from the stomach, and consequently without irritating the oesophagus and gastric mucous membrane. In this manner they may be passed successively at one sitting and may serve the purpose of diagnosis or treatment for which they are intended.

The construction of these instruments is essentially the following: The tubes used for this purpose are small, smooth rubber tubes (length, thirty-one inches; diameter, a fifth of an inch). In order to give them sufficient stability to enable them to be passed through the primary tube they inclose in the entire length a piece of whalebone, securely attached at both ends.

![Diagram](image)

In the case of the illuminating apparatus the small tube contains, besides the whalebone, the wires necessary for the intragastric lamp (E). To the upper end of this tube is cemented a metal tube, to which is attached a cube of hard rubber (F) possessing cups for the pin connections of the wires going to the battery. Surrounding the metal tube is an adjustable metallic clamp (G), supporting a tubular rubber stopper, by which the lumen of the larger stopcock (B) may be securely closed.

The position of the tubular stopper can be changed by shifting the clamp (G), thus enabling the operator to know exactly to what distance the light projects beyond the lower opening of the primary tube. The tubular rubber stopper, by securely closing the larger stopcock (B), enables the operator to inflate the stomach through the smaller stopcock (C) at the same time that the light is in position in the stomach, without removing any portion of the primary apparatus.

The advantage of this arrangement to both patient and operator can readily be seen. The interior structures of the secondary tube (D) never come in contact with any of the gastric or lavage fluids, so that absolute cleanliness, durability, and greater brilliancy of the light itself are secured. I believe that the discredit into which the intragastric lamp, as a means of diagnosis, has fallen in recent times is largely due to the fact that it has never been possible to control the stomach itself during the operation.

Most physicians have no time for, and most patients rebel against, the successive introduction of various stomach tubes at one sitting; consequently the organ was usually examined under unfavorable conditions. It was either filled with turbid fluid, or its walls were in a collapsed condition, and both patient and physician grew tired of the repeated passage of the several tubes necessary to prepare the stomach for the examination.

With this instrument simply one tube comes into contact with the patient. The stomach is cleansed by lavage through this primary tube and a desirable quantity of clean water is left in for the necessities of the light. The secondary lamp tube is passed without any disagreeable sensations to the patient and the opening to the larger stopcock is closed by the tubular stopper. The operator can now examine the stomach under any condition of distention by either introducing water or air through the smaller stopcock (C).

No dark room is necessary for the examination, as an apron made of black cloth can be fastened around the patient's waist and the examination conducted beneath this. It is also desirable to employ a battery composed of several dry cells connected by a switchboard, so that the strength of the light may be regulated at will. This arrangement will in part overcome the objections hitherto imposed upon the light, that adjacent intestinal structures were incorporated in the picture, for by increasing or decreasing the quantity of light the exact position of the lamp itself can be determined.

I said at the commencement of this paper that it was not safe in examining the stomach to rely upon any one method; but the inconvenience attendant upon the various methods and instruments is what most patients object to, and to the active practitioner the element of time is of great importance. To determine these factors rapidly with this instrument the following routine is advisable. It involves the method of Leube for the determination of the motility of the stomach, that of Penzoldt for locating the greater curvature and the tone of the gastric walls, that of Bouveret for establishing its size and location, and the transillumination method of Einhorn. These are the quickest methods for clinical purposes, and, taken in combination, yield sufficiently accurate results.

The patient is given the usual Leube test meal in the morning, and told to present himself for examination seven hours afterward. The primary tube is passed and the stomach washed to determine the presence of any residue of food. Having completely emptied the organ of all its contents, the patient is placed in an erect position and the gastric region percussed rapidly. Water is now introduced in one-pint quantities, the tone of the walls determined, and the greater curvature located according to Penzoldt's methods. Having finished
this operation, the fluid can be siphoned off and the stomach filled with air through the smaller stopcock. Its size is thus determined according to the method of Bouveret. This operation finished, the intragastric lamp can be introduced through the primary tube, after having allowed the escape of the air, in order to confirm the conclusions arrived at by the previous methods.

All this can be accomplished in a very short space of time, and without great inconveniences to the patient, for only one gastric tube has been really passed. Other methods, such as those of Dehio and Rosenbach, can be incorporated in the same, if it is found to be advisable. In this manner we determine at the same time the motility, the size, the location of the stomach, and the muscular tone of its walls.

So far as irritability of the gastric mucous membrane is concerned, it will usually be found that the previous extraction of test meals will have sufficiently prepared the patient for manipulation, for the physical examination of the stomach should be attempted only after its secretory functions have been determined previously. This should be repeated several times, in which case it assures not only the success of the physical examination, but also that of the chemical examination of the gastric contents. Cases will be found at times where the irritability of the stomach is so great and so constant that no examination whatever can be made. But even in these cases a course of primary calming treatment will often render the examination possible.

The remaining sections of this instrument consist of the intragastric douche and electrode. Their construction is the same in principle as that of the lamp, and they are applied through the primary tube. The advantages of this method of application can again be seen. Here, as with the lamp, the stomach can first be prepared for treatment by means of the primary tube.

The intragastric douche consists of the secondary tube (D), carrying at its lower end a hard-rubber capsule (N), the perforations of which are so minute as to produce a needle spray of universal direction. The external end of the tube is armed with a metallic tube, to which is attached the movable metallic clamp (G), supporting the tubular rubber stopper. The douche fluid is forced through the secondary tube under pressure from an ordinary Davidson syringe. The diameter of the secondary tube is such that it passes easily through the primary tube, but, should there be any constriction of the primary tube at any point, it is well to apply a little benzcoated vaseline.

In the old form of instrument, which consisted simply of a closed stomach tube perforated at its lower end by numerous openings through which the douche fluid was forced from a fountain syringe, it was never possible to get very beneficial results, owing not only to the difficulty of manipulation but also to the uncertainty of its action.

In order that the intragastric douche may be beneficial at all, it is first necessary to prepare the stomach for its reception. Herefore, if this was done it was only possible by first passing an ordinary lavage apparatus to cleanse the cavity of the organ, removing this and passing the douche tube, which was finally attached to the fountain syringe. Even after this complicated process, it was never possible to count upon the efficiency of the douche, for the perforations of the tube often became plugged with mucus in their passage through the esophagus and there was no douche at all, or, what is more important still, the walls of the stomach were not in proper condition to receive it.

Even if the cavity of the stomach was thoroughly emptied and cleansed by the operation of lavage, this very act of itself excluded the possibility of effectiveness on the part of the douche by leaving the organ in a state of collapse. This state of collapse, however, is entirely antagonistic to the efficient action of the douche, for with the mucous membrane creased into numerous folds, the douche fluid could never reach their interstices, and half the effect was consequently lost. On the other hand, if sufficient lavage fluid was left in the cavity of the stomach to distend it, there was no room left for the douche fluid.

In order that the intragastric douche may be effective, it is absolutely necessary that the stomach be clean, empty, and partially distended. It was always possible under the old form of operating to clean and empty the stomach by the lavage tube; also, by removing the funnel and attaching a double rubber bulb, to inflate it. Having done this, it was necessary to remove the lavage apparatus and insert the douche tube. By the time this had been accomplished, however, the air had probably escaped either by the pyloric or cardiac orifices and the walls were again relaxed. Even though the air did remain in the stomach long enough to insure a proper action on the part of the douche, its very presence interfered with the operation, for, being gradually displaced by the douche fluid, the organ became distended and the operation had to be stopped before a proper effect could be secured.

In the great majority of cases, however, all these precautions were never taken. The douche tube was simply passed, the openings of the tube became plugged.
with mucus, the stomach itself was unclean and relaxed, and the whole operation proved a failure; hence the intragastric douche, while still mentioned in all the books as a therapeutic measure in certain forms of chronic gastric diseases, has generally been abandoned as too complicated and ineffective.

Intragastric douching must of all things be practical and simple. It has been my object in the construction of this instrument to secure these two elements of success. The steps in the operation are the following: The primary tube (A) is passed and the stomach cleansed by lavage; after removing the funnel attachment the secondary douche tube (D) is passed through stopcock B, the lumen of which is securely closed by the tubular rubber stopper (G). Air is now forced into the stomach through the smaller stopcock (C) until a moderate degree of distention is secured. This done, the process of douching begins by means of the Davidson syringe. The force of the douche can be regulated by the pressure employed. As the air in the stomach becomes displaced by the douche fluid, the former can be allowed to escape through the smaller stopcock. In this way all overdistention is avoided, and the pressure in the stomach remains practically stationary.

The whole operation can be repeated if necessary by removing the douche tube, siphoning off the fluid, and beginning over again. This is accomplished without inconvenience to the patient, for the primary tube remains in place and the douche tube never comes into contact with the patient. The whole process consists then of lavage, distention, and douching, all of which are carried out without more annoyance to the patient than an ordinary operation of lavage.

The three principal effects sought for by intragastric douching are cleansing, medicinal, and dynamical. These names indicate in part the classes of cases to which douching may be applied. I refer especially to all those chronic gastric diseases where lavage has hitherto been employed. This would include cases of atony, with or without dilatation; cases of excessive fermentation; cases of chronic gastritis with excessive secretion of mucus; in fact, all disorders in which the stomach should be thoroughly emptied of its contents and cleansed.

It has been my experience that in many of these cases lavage has failed in its purpose, and naturally so, because it is manifestly impossible to cleanse more than the lower segment of the stomach by this operation. It may be possible to remove the residue of food and any excessive mucus found in the lower segment, but the folds of the upper segment never come into contact with the cleansing fluid. It is exactly in these folds of mucous membrane, however, that the organisms necessary to fermentation lurk. To fill the stomach sufficiently with lavage fluid to distend these folds is not only impossible, but deleterious in its effect in cases of atony and dilatation, on account of the very volume of the fluid necessarily employed; consequently, lavage often fails in one of its most important objects—namely, the thorough disinfection of the stomach.

Hence the advantage of the douche applied in this way as an adjunct to lavage is clear. The stomach is first emptied of its contents by the ordinary method, the douche tube is passed, the organ partially distended with air, and the surface of the mucous membrane thoroughly douched with whatever disinfecting solution may be deemed advisable. The quantity of this solution need not be large—not more, in fact, than half a pint. Should even this quantity be deemed objectionable, it can always be removed by means of the primary tube after the operation of douching has been completed.

For medicinal purposes the douche can be employed in those cases where there exists a loss of secreting power on the part of the stomach. The flooding of the cavity of the stomach in order to stimulate secretion is well known. For this purpose solutions of dilute hydrochloric acid, bicarbonate of sodium, common salt, and bitter tinctures have been employed, but the work has never passed the experimental stage.

How much more effective would an energetic douche of these solutions be in a stomach whose walls have been partially distended, so that the fluid can come into intimate contact with the surface of the mucous membrane! There would be in addition a direct dynamical effect on the muscular structures of the organ. I need not call attention to the commonest form of chronic gastric diseases, the so-called "weak stomach," a combination of deficiency in secretion, loss of tone of the muscular structures, stasis of food, and the consequent fermentation.

There can be no danger from either the volume of the liquid or from toxic effects, for any excess of fluid can easily be withdrawn through the primary tube.

As a stimulant to muscular activity the intragastric douche should give good results. There is no direct dynamical effect from the operation of lavage. It acts indirectly upon the muscular structures of the stomach by relieving them of their burden. Add to this the direct stimulating quality of an energetic intragastric douche, after the bulk of the gastric contents has been removed, and the effect will be doubled.

It is internal hydrotherapy, so to speak. Here a trial of fluids of high or low temperature would be in place. The quantity of the douche need be small, while the time and force employed are absolutely under the control of the operator. There can be no danger of overdistention, so that it can be safely employed in all disorders emanating from a loss of muscular tone of the stomach.

Heretofore the intragastric douche has been employed largely in neurotic affections of the stomach. I refer especially to hyperesthesia of the gastric mucous membrane resulting in a line of nervous phenomena, such as gastralgia, irritability, and nausea. Owing to the construction of the old form of douche, the effect...
was perhaps largely a moral one, for it was never possible to predict a certain action on the part of the douche or that the douche fluid came into intimate contact with the surface of the mucous membrane. These doubts are eliminated in the new form of instrument. The primary tube is passed, the stomach is slightly inflated, and the douching with any sedative solution takes place.

The remaining portion of the instrument consists of an intragastric electrode. Its construction corresponds in the main to that of the lamp and douche, and it is introduced into the stomach through the primary tube.

The electrode consists of the secondary tube (D), to the lower end of which is cemented a platinum electrode incased in a perforated hard-rubber capsule. The external end of the tube is armed with a metallic tube, the tubular rubber stopper, and the clamp attachment (G). Here also the stomach can be thoroughly prepared for the action of the current by lavage through the primary tube.

The whole instrument is simple and clean. The external or primary tube can be cleansed and disinfected as easily as any ordinary stomach tube; the double hard-rubber stopcock is detachable and can be rendered thoroughly aseptic. No gastric contents can collect in any portion of this tube. The secondary tubes containing the various attachments for lighting, douching, etc., are sealed so that the gastric contents do not reach their interior; their exterior surfaces can be thoroughly cleansed. The construction of the various parts is simple, so that they can be repaired quickly and without great expense.

There is no more danger attendant upon the use of this instrument than that attached to the ordinary lavage apparatus, and no more skill is required for its manipulation. It calls for no more toleration on the part of the patient than the usual form of gastric tube, and for thorough examinations in obscure cases it saves the patient much material discomfort, as only one tube need be passed. A little education on the part of the patient is required for all gastric examinations, but, after one or two test meals have been extracted for the determination of the secretory functions of the stomach, the patient in the majority of cases is prepared for the physical examination.

The principles involved in the application of the various parts of this combination of instruments are well known and have been in use for a long while. It has simply been my object to render them more accessible and thorough, and more possible of application; further, the instrument is intended to save time to the examiner and discomfort to the patient.

Before closing, I must extend my thanks to Mr. Eugene W. Caldwell for his ingenuity and suggestions in overcoming the mechanical difficulties of construction. I must also express my appreciation of the work of my assistant, Dr. Lewis N. Foote, for his attention to the work of testing the various appliances at the Vanderbilt Clinic.

SOME PRACTICAL NOTES UPON DISEASES OF THE RECTUM.*

By LEWIS H. ADLER, JR., M.D.,
PROFESSOR OF DISEASES OF THE RECTUM,
PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE;
PROCTOR TO THE PROFESSOR OF ANATOMY,
MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA, ETC.,
PHILADELPHIA.

RECENTLY a physician from the West had occasion to consult me regarding some trouble about his rectum. Upon his second visit he remarked that he had frequently requested patients to mount his examining table for the purpose of making a rectal examination, but that it was not until he was obliged to go through the personal ordeal in my office that he fully realized the reason for the hesitancy that most patients exhibit in assenting to and going through an examination of this portion of the body. These remarks, coming from a physician, served to emphasize to me the necessity for the employment of the utmost tact and gentleness in dealing with all patients, especially with those afflicted with disease of the rectum and anus.

All persons suffering from diseases of the rectum are especially prone to be depressed and are more or less nervous. This fact, combined with the natural restraint experienced in paying a first visit to a physician, should be realized by the examiner, and in order to aid such persons to recover their composure it is best to encourage them to give the history of the disease in all its details. While this consumes time, the more important object is accomplished of securing the cooperation of the patient in the subsequent steps of the investigation—to wit, the digital exploration of the bowel, without which a positive diagnosis can never be made. These remarks are especially applicable to the treatment of females. Assent to a vaginal examination is much more readily obtained than is the consent to inspect the seat of rectal trouble.

While abruptness or undue haste on the part of the medical examiner will usually frustrate all attempts to gain the consent of a female patient to undergo an examination, it is a fact that, no matter how gentle and forbearing the examiner be, some patients will remain

* Read at a meeting of the Medico-legal Society of Philadelphia, October 31, 1899.
obstinate and resist all efforts pertaining to a local examination. The following instance is a case in point: Several years ago I was consulted by an elderly woman who gave a history pointing toward some rectal trouble, which she stated had existed for a considerable length of time. She also remarked that she was certain that all that ailed her was "piles," I finally suggested that a local examination was necessary, whereupon she became quite indignant and informed me that she had consulted as many as fifteen doctors about her condition, and that not one of them had been guilty of requesting, much less insisting upon, an examination. As I failed to convince her of the error of her way, she left my office in a rather unenviable frame of mind. The verification of her statement regarding the number of physicians she had seen was not possible or even necessary, but I have no doubt that she was correct in stating that she had been under treatment for a considerable length of time for some rectal lesion, which was treated by more than one physician without any attempt being made to visually inspect the parts involved, much less to explore them with the finger.

The following remarks of Dr. Charles B. Kelsey are so in accord with my own views, as well as borne out by experience, that I am sure they will bear repetition here in connection with the history of the case just narrated: "The symptomatology alone may be of great value in the diagnosis of rectal disease; it is almost never sufficient in itself for a diagnosis. There is a train of symptoms common to almost all diseases of this part, and which infallibly point to trouble of some kind, but they do not tell what that trouble is. The pain of a fissure is sometimes almost diagnostic, but it does not tell what troubles may be associated with the fissure; and so it is in every other rectal affection. For this reason the practitioner who attempts to treat a case of disease of the rectum without first making a direct examination, both visually and digitally, uselessly risks his reputation as a diagnostician; and in my own practice I am guided by the simple rule that patients, male or female, who have not yet come to the point which makes them willing to submit to an examination have not yet reached a point which admits of treatment. An examination, especially in women, is sometimes, though not often, difficult to obtain, and the dread of it keeps many sufferers from seeking relief; but still the rule I have laid down is the only safe one, and the surgeon who allows himself to be persuaded into 'recommendating something for piles' will sooner or later have a mistake in diagnosis laid to his charge, nor will the fact that he was moved by consideration of the patient's sensibilities save him from blame."

I shall now invite your attention somewhat briefly to a consideration of some of the various forms of rectal diseases.

---

* Disease of the Rectum and Anus: their Pathology, Diagnosis, and Treatment; fourth edition, New York, 1893, pp. 41, 42.

---

Congenital malformations of the anus and the rectum, while by no means a common occurrence, occur often enough (one case in about eleven thousand births) to justify attention being called to the necessity for every newborn child being carefully examined at the time of its birth. If this step were made a routine practice, subsequent mortification would be avoided in having the nurse or some member of the family call the doctor's attention to the fact that the child had not had a movement of the bowels since its birth, and that they were afraid that something was wrong with the child's parts.

Proctitis (inflammation of the rectum, involving one or all of the four coats of the bowel) and periproctitis (inflammatory changes occurring either primarily in the loose areolar tissue on the outside of the rectum or as a secondary process due to an extension of a procitis) are mentioned because of their marked tendency to lead to suppuration, and suppuration in or around the rectum is often followed by a fistula. I should like to dwell upon this subject did time permit; let it suffice for me to urge upon those attempting to deal with supplicative processes in the neighborhood of the rectum to avoid poultices and to lay the affected parts freely open as soon as the formation of an abscess is recognized, even before pus occurs. The mistake usually made when the knife is employed is that of making the incisions or incision too small.

In dealing with abscesses around the rectum it is also essential to have free drainage, and that the incision should lay open most freely all tissue that has even the semblance of being indurated. This is the only secret, if such it may be called, in the successful treatment of abscesses in this locality and in the prevention of a fistula.

In all cases of fistula in ano it is to be remembered that the sinus may be the result of a stricture of the rectum, and under such circumstances the usual treatment directed for the relief of a fistula will not suffice for a cure. A digital examination of the bowel will, as a rule, prevent such an error being made.

To the average practitioner the internal variety of fistula is the most difficult to recognize, as it has no external opening. It is also the most treacherous form to deal with unless promptly diagnosed. It frequently arises from a spiculum of bone, a sliver of wood, or a fish bone being swallowed and then lodging in the constricted part of the anus. More than once patients have consulted me complaining of the sudden onset of pain at the lower portion of the bowel, and upon making a digital examination I have found such foreign bodies. The prompt removal of the offending substance will prevent the formation of a fistula.

In dealing with the subject of fistula it may be wise to mention that the internal opening in most cases is to be found between the two sphincter muscles, and not, as most practitioners seek it, higher in the rectum. A very
simple means of ascertaining the location of the internal orifice of a fistula is by the injection of some fluid, such as peroxide of hydrogen, milk, a solution of crocin, or one of permanganate of potassium. These substances may be injected into the external opening (it is only in cases in which an external opening exists that this method is applicable), and if an internal communication with the bowel exists the fluid used will be seen oozing out of the anus or else found within the rectum.

It should always be borne in mind that a fistula may not be connected with the bowel, but with the genito-urinary tract. The escape of urine through the sinus will settle the question.

The question is frequently asked as to whether it is prudent to operate upon a patient suffering from pulmonary phthisis. If the lung trouble is active, as in cases of so-called galloping consumption, my answer would be in the negative; otherwise, operate.

It is not essential in all cases of fistule to etherize the patient for the operative procedures required to effect healing of the tract, nor is it necessary to put the patient to bed before a cure can be effected. Simple cases of fistule, or cases in which a general anaesthetic is contraindicated, may have the parts rendered as aseptic as circumstances will permit, and then, under the influence of a local anaesthetic, such as cocaine or eucaine, the tract may be painlessly opened and a cure result; the patient not being confined to bed, but advised to rest as much as possible until the wound has healed. Personally, I have employed only cocaine for this purpose, and that drug I use in the strength of a two- to four-per-cent. solution—never stronger.

The diagnosis of ulceration of the rectum and of the sigmoid flexure must of necessity be attended with more or less difficulty, but the presence of an ulcer may be suspected when the symptoms of intestinal inflammation persist for some time, and especially when they are accompanied by haemorrhage, diarrhea, and more or less mucoid discharge. Frequently, cases diagnosed as dysenteric attacks are in reality due to the presence of an unrecognized ulcer, either of the rectum or of the sigmoid flexure.

Irritable ulcer or fissure of the anus is a disease entailing such extreme misery to the patient, and its symptomatology is so characteristic, that it is often a matter of surprise to me to see patients so afflicted go so long without the nature of the affection being recognized by the medical attendant. In all cases presenting a history of pain, which is paroxysmal in character and always associated with the act of defecation, though not necessarily accompanying the actual pas-sage of the motion, but which comes on shortly afterward with great intensity, and is succeeded by a dull, gnawing, and an extremely distressing sensation, situated immediately within the anus, the presence of a fissure should at least be suspected, and a careful examination of the patient's anus and rectum should be made. The pain alluded to frequently lasts for many hours and completely incapacitates the sufferer from following any occupation.

Many cases of fissure of the bowel are treated by the family physician with an opiate in order to relieve the distressing suffering. Nothing could be employed that would do more harm than this much-abused drug. The best remedy to use is iodiform, preferably in the form of a ten-grain suppository, of which one should be carefully inserted into the rectum half an hour before an expected movement of the bowels and another immediately after the passage has occurred.

Stricture of the rectum, malignant or otherwise, may exist for a long time without even the patient being conscious of its presence or of suspecting that there is anything wrong with the bowel. The symptom so commonly considered as being pathognomonic of the presence of stricture—namely, the narrow or tapelike shape of the feces—may be associated with a fissure, or with any other lesion of the rectum which occasions an hypertrophy of the sphincter muscles.

Fistulae and haemorrhoids, jointly or singly, often coexist with a stricture of the rectum. Under such circumstances should the medical adviser not digitally examine the rectum, but conclude from inspection of the parts only that the patient has haemorrhoids or a fistula, or both, and so inform the person, he places himself in a well-merited position of being severely censured when the true condition is recognized. I have personal knowledge of a patient who was operated upon for a fistula and haemorrhoids by a very reputable surgeon, and in the course of time, as the case did not progress favorably, a consultation was held, when the true condition of affairs was ascertained by finding a malignant stricture of the rectum within easy reach of a digital exploration of the parts.

Syphilitic conditions of the anus, and more especially of the rectum, are rather rare, at least in this country. The possibility of this trouble being present should not be overlooked in dealing with affections in this locality, especially when the patient is a female, as in this sex the disease may be contracted as a result of self-inoculation from similar disease in the vagina or about the vulva, the discharge trickling down over the perineum, and so infecting any excretions of the part that may be present; or it is possible that the accidental contact of the penis during coition may be the means of conveying the infection.*

Mucous patches about the anus are of comparatively frequent occurrence, and so are the so-called condylomatous excrescences. In congenital syphilis the only common manifestation at the anus is the mucous patch, or, what is more frequent, numerous fissurelike ulcers.

Prolapsus recti in children is often occasioned by mothers attempting to establish regularity of the bowels

* Charles B. Ball, P. R. C. S. I. The Rectum and Anus; their Diseases and Treatment. Philadelphia, 1887, p. 179.
by insisting upon the child sitting and straining on a commode for half an hour at a time. Phimosis, adherent prepuce, and stone in the bladder are often the cause of a prolapse of the bowel. The presence of seat worms may also occasion this malady. More than once I have seen a polypoid growth in a child which had been treated for a simple prolapse. The latter condition was only relieved by the removal of the polypus.

**Hemorrhoids**, though the most frequent of all rectal diseases, will be alluded to only briefly, as justice cannot be done otherwise to the scope of this article in the time allotted. The division of hemorrhoids into external and internal is generally known and accepted by the profession. I have no doubt that it is also known that in reality, as well as in name, the one belongs to the exterior of the rectum and the other to within the bowel. In nearly all cases patients endeavor to reduce both varieties of piles by pushing them into the rectum, in this manner aggravating the external form and increasing their sufferings. I am sorry to add that some of these patients have acted in this manner under advice from medical men. Had these physicians taken the trouble to examine their patients I am sure that no such advice would have been given.

All cases of hemorrhoids do not require operative interference. In the formative stage of hemorrhoids frequent ablutions of the part with cold water will allay, if not abort, inflammatory tendencies of the veins, which otherwise finally lead to piles. On the other hand, in those cases which demand operative measures, I am not in sympathy with the advice so often given to postpone operation until the acute inflammation has subsided. It is when the patient is suffering that consent will be most readily obtained, and it is owing to such advice that these patients finally drift into the hands of the quacks.

External hemorrhoids, when inflamed or otherwise, can always be painlessly removed under cocaine anesthesia, and it is at the time that they are inflamed that the operation does the most good, for it not only radically removes the trouble, but it quickly alleviates the intense suffering which their presence otherwise occasions.

Hemorrhoids are sometimes a symptom of some more remote and more important visceral disease, such, for instance, as cirrhosis of the liver, uterine displacements, etc. Under such circumstances, the surgeon who looks at these cases with the eye of a specialist and directs his treatment solely to the rectum will sooner or later come to grief as well as run the risk of doing his patient irreparable harm.

**Benign neoplasms** of the rectum I mention because of the difficulty sometimes experienced in ascertaining the presence of a polypoid growth. If the tumor is round, has the usual velvety feel of the normal mucous membrane of the bowel, and is pedunculated, the average practitioner will fail to find it, because, in his examining finger. The correct way of ascertaining the presence of such a growth is to carry the finger well up the bowel away from the side to be explored, and then, by steady pressure, to sweep the finger downward, continuing this procedure all around the bowel. In this manner, if a polypus is present and within the reach of the finger, it will be caught between the finger and the wall of the rectum.

Finally, a brief word as to one of the most frequent causes, as well as the prime cause, of all rectal diseases—constipation. The modern way of living in crowded cities and in overheated and poorly lighted and ill ventilated houses, taken in conjunction with the adulterated and artificially prepared food stuffs eaten, together with the hurry with which the average man bolts his food and the lack of time assigned for not taking any but little outdoor exercise, are among the principal factors in producing this condition. Even infants are not exempt. I think that you will all agree that constipation is on the increase, and that the percentage of increase is by no means small.

1610 Arch Street.

**DIPHTHERIA:**

**REMARKS ON CLINICAL DIAGNOSIS AND TREATMENT.**

By HERMAN B. SHEFFIELD, M.D.,

Physician to the Metropolitan Dispensary and Hospital for Women and Children, etc.

The object of this paper is to emphasize the writer's observations on the essential early clinical signs of diphtheria as distinguished from other similar affections and to detail the method of treatment employed by him with almost uninterrupted success. Volumes are being filled with dissenting views on the value of bacteriology in the diagnosis and on that of antitoxine in the treatment of diphtheria; too little space is devoted to the clinical experience with this disease. The discussion of this subject from a clinical point of view may, therefore, commend itself to the profession.

I. Diagnosis. 1. Pharyngeal Diphtheria.—(a) Diphtheritic Membrane: In pharyngeal diphtheria the pseudo-membrane appears as a small, uneven, grayish-white, slightly elevated patch upon the inner tonsillar or faucial surfaces of the throat. The deposit augments by quick spreading, reaching within a few hours the posterior wall of the pharynx, and, in severe cases, the Eustachian tubes, nares, and, very rarely, the conjunctiva. Anteriorly the pseudo-membrane attacks the palatal arch and uvula. It may spread downward into the larynx or alimentary canal. The surrounding uncovered areas are grayish in color, due to overcrovoring of leukocytes, nuclei, and mucus beneath. The tonsils are, as a rule, but slightly enlarged. The deposit, if removed, leaves a raw, bleeding surface and reforms rapidly.
In follicular amygdalitis the deposit begins as one of more white, small pellicles upon the middle or anterior portion of the tonsil. The pellicles, at first distinctly isolated, gradually coalesce, forming elevated patches. They are limited to the tonsils, may easily be removed, and reform slowly. The tonsil, usually one, is moderately enlarged, sometimes previous to the appearance of the deposit.

In parenchymatous amygdalitis the tonsil is greatly enlarged, often displacing the uvula. It is bluish in color and doughy in consistence. The deposit, at first white, soon becomes yellowish, resembling the “point” of an abscess.

In herpetic amygdalitis the deposit begins with minute vesicles, which have a tendency to burst and leave superficial ulcers. This form of amygdalitis is at times accompanied by stomatitis. Otherwise it resembles follicular amygdalitis.

In necrotic amygdalitis the tonsils are moderately enlarged and the deposit lies deeply imbedded within the structure of the mucous membrane. The deposit, if removed, leaves behind a deep ulcer—sometimes gangrenous—surrounded by a distinct red zone; it spreads, as a rule, from one tonsil to the other by way of the anterior pillars and palatine arch, frequently attacking also the uvula.

(b) Submaxillary Glands: The submaxillary glands in diphtheria are greatly involved. They are large and hard, assuming the shape of a large walnut, and can be easily seen bulging out. They are very painful to the touch.

In follicular and herpetic amygdalitis the glands are moderately enlarged, softer in consistence and less painful to the touch than in diphtheria.

In parenchymatous amygdalitis the glands are moderately enlarged and diffused, the swelling often extending as high as the ear.

In necrotic amygdalitis the glands differ but slightly from those of diphtheria and can not be relied on as a differential point of diagnosis.

(c) Early Constitutional Symptoms: Excepting the presence of albumin in diphtheritic urine, none of the early constitutional symptoms are characteristic of diphtheria. Indeed, they are frequently less pronounced in diphtheria than in the other throat affections, unless the former is complicated by streptococce infection. The temperature in diphtheria is, as a rule, moderate, about 101° to 103° F., and continuous. The pulse is feeble and quick and soon gives signs of exhaustion. The face, as a rule, is pale. Swallowing is difficult, but not very painful, due to partial degeneration of the muscles of deglutition and their nerve supply. Albuminuria is invariably present from the earliest beginning of the disease and is of great significance in the differential diagnosis.

In the various forms of amygdalitis the temperature is quite high, especially toward evening, often reaching 105° F. The face is flushed. Deglutition is painful and difficult as a direct result of soreness and sensitivity of the tonsils. Albuminuria is usually absent.

The diagnosis of scarlatinal angina is at times very difficult, and in our experience we have succeeded well by judging it from the severity of the attack. We have thus been in the habit of pronouncing every case resembling amygdalitis as scarlatinal angina, while some cases present the characteristics of diphtheria, especially when the spreading of the pseudo-membrane begins a few days after the development of the rash. We must refrain, however, from considering this rule as the best one.

2. Laryngeal Diphtheria.—Laryngeal diphtheria can only be mistaken for non-diphtheritic membranous laryngitis, also known as croup, which is on the other hand entirely distinct from spasmodic laryngitis, a mild catarhal inflammation of the mucous membrane of the pharynx or larynx without the formation of a pseudo-membrane. In speaking of non-diphtheritic membranous laryngitis I am fully conscious of the manifold denials made by advanced clinicians as to the existence of such a non-diphtheritic disease; here again I am merely guided by the observations made in my own practice without attempting either to confirm or dispute the views of others, and, while the exact distinction is associated with extraordinary difficulty, I believe I have been successful in making a correct diagnosis with the aid of the following differential points:

<table>
<thead>
<tr>
<th>Membranous Diphtheritic Laryngitis</th>
<th>Membranous Non-diphtheritic Laryngitis</th>
</tr>
</thead>
<tbody>
<tr>
<td>Distinctly contagious, giving also a history of contagion.</td>
<td>Not contagious.</td>
</tr>
<tr>
<td>Early enlargement of the submaxillary glands</td>
<td>Submaxillary glands, as a rule, not involved.</td>
</tr>
<tr>
<td>Diphtheritic patches are found, as a rule, on the fauces and posterior nares.</td>
<td>The fauces may be covered with a mucus exudation, which can easily be wiped off.</td>
</tr>
<tr>
<td>Early treatment, including intubation, neither aborts the disease nor always prevents a fatal issue.</td>
<td>As a rule it does.</td>
</tr>
<tr>
<td>Albuminuria usually present.</td>
<td>Absent.</td>
</tr>
</tbody>
</table>

I may also mention that pharyngeal or laryngeal syphilis in childhood, if accompanied by an acute attack of amygdalitis, is apt to be mistaken for diphtheria, and great skill and caution are often required to eliminate the latter affection. In early diagnosis the history of the case and the usual presence of syphilitic manifestations on other portions of the body are the only reliable differential signs.

II. Treatment. 1. Pharyngeal Diphtheria.—Bearing in mind the facts that diphtheria is primarily a local disease and that infection of the whole system takes place rapidly through absorption of the diphtheria toxine formed at the originally infected spot; furthermore, that a fatal issue of the disease is due either to septic poisoning or, more rarely, to obstruction of the air-passages, the following procedure commends itself:
(a) Endeavor to subdue the hyperaemia and excessive exudation in the throat in order to avoid respiratory obstruction.

(b) Destroy at the earliest moment the diphtheria bacilli at their point of entrance in order to prevent the excessive formation and immediate absorption of the diphtheria toxin.

(c) Increase the power of resistance of the patient and administer such remedies as will combat or neutralize the toxic substances, thus preventing their dissemination in the internal organs of the body.

(d) Promote the action of the lymphatic system, kidneys, and bowels in order to rapidly eliminate the poisonous products.

Under the first and second headings must be classed all germicides, care being exercised that they do not act simultaneously as active escharotics. We have been very fortunate with the following two combinations:

No. 1.

B: Glycerin. papoid. .................. 5iv; Acid. carboilic, | ā ā ....... gr. viij; Pulv. camphor., | ā ā . . . . . . . . q. s. ad 1.5j.

This is applied to the throat by means of a cotton swab every two hours—changing the swab each time—diminishing the frequency of applications with the abatement of the severity of the symptoms.

No. 2.

B: Hydrogen. peroxid. .................. 5iv; Sodii borat. .................. 5ij; Glycerin. .................. 1.5j; Aquæ roseæ .................. q. s. ad 1.5iv.

One tablespoonful to be instilled into the nose every two hours in the presence of diphtheritic membranes in the nares, and every four hours in their absence.

The third and fourth indications must be met with plenty of good nourishment, haematomata, nerve and cardiac stimulants, diuretics and laxatives. I may state here that in administering stimulants I never wait until cardiac debility sets in, but employ mild stimulation from the earliest beginning of the disease, thus increasing the power of resistance of the patient and preventing the micro-organisms from impregnating the internal organs. Feeding of little patients is as difficult as it is important. But I have frequently been surprised to see how bravely a child would battle through a severe attack of an acute disease without a mouthful of food for days. The fact that there is, as a rule, complete anorexia present tends to indicate that it is probably a provision of Nature to starve the micro-organisms lodged in the alimentary canal. However this may be, all efforts should be made to nourish the patient with milk, beef tea, "prepared food," etc., and in case the same can not be administered by the mouth, nutrient enemata should be resorted to.

Of internal medicinal agents I am in the habit of prescribing:

No. 3.

B: Tinet. ferri chlorid., } ā ā ....... 5ij; Tinet. myrrhæ, } Glycerin. .................. 5ij; Syr. zingiberis. .................. q. s. ad 1.5ij.

One teaspoonful to be given every three hours to a child three years old.

No. 4.

B: Strychninae sulph. .................. gr. 4; Liquor. ferri et ammon. acet. ........ 1.5ij.

One teaspoonful to be given every six hours to a child three years old.

Any untoward symptoms arising must be combated accordingly. I have rarely had occasion to use antipyrines, and I have found that a small dose of any of the stimulating coal-tar products always answered well to reduce the temperature and relieve pain. A laxative administered once a day is useful. In marked irritability of the child, sodium bromide, combined at times with a small dose of chloral, is very serviceable.

2. Laryngeal Diphtheria.—This, the most dreaded form of diphtheria, is, as a rule, not accessible to local treatment. If any diphtheritic deposit is visible along the fauces, the first mixture may advantageously be applied. I always order cleansing of the nose with the second solution. In severe cases intubation must be resorted to early, and in this way late tracheotomy can be dispensed with. The internal remedies enumerated above are certainly of undoubted benefit, and I believe that severe attacks of diphtheria can be averted by their administration. When intubation is performed, and the administration of liquids by the mouth must be avoided, strychnine should be given hypodermically. For the reduction of swelling of the submaxillary glands, iodine ointment with ten per cent. of leishyl is an excellent local remedy. Before the discovery of antitoxine I had been very successful with the method of treatment outlined under pharyngeal diphtheria, together with inhalations of antiseptic vapors. Influenced by the numerous favorable opinions on antitoxine, I have recently begun to administer the serum in every case of laryngeal diphtheria and can report good results. I am not prepared, however, to state how much of the success can be attributed to the antitoxine and how much of it to the local and internal remedies employed in connection with it.

THE SURGICAL TREATMENT OF PHthisis.

By WALTER C. WOOD, M.D.

On first consideration, the phrase the surgical treatment of phthisis seems an absurd proposition, yet on investigation of the recent literature it is found to merit serious consideration. The work already done
rests on well-established surgical principles and demands the respect of the most conservative among us. It is but a part of the general subject of the surgery of the lung, which is now attracting attention, as did the surgery of the abdomen several years ago, and we hope it will bring equally beneficial results; yet it is no new thing.

Drainage of a pulmonary cavity was probably first successfully done by Baglioni, in 1710, but we know more definitely that in 1844, Hastings, of England, and Storck, of Germany, incised and inserted drainage tubes in apex cavities of tubercular lungs and into pulmonary abscesses. In 1873 Mosler tapped such cavities and injected iodine. At the Congress for the Study of Tuberculosis, held at Paris in 1891, Poirier and Jouonneau reported twenty-nine cases of incision and drainage of apex cavities, with four cases considered cured, fifteen improved, nine deaths, and one case not traced. In 1892 Tuffier, of Paris, reported a case of resection of a right apex for tuberculosis, and the patient was known to be alive and free from phthisis two years afterward. The last procedure that I am acquainted with is that proposed by Dr. J. B. Murphy, of Chicago, at Denver in June, 1898, viz., the defunctionization of the lung by the introduction of nitrogen gas into the pleura, thus causing compression.

There are, therefore, four plans to be considered under the subject of the surgical treatment of phthisis: First, aspiration of cavities and direct medication; second, pneumonotomy, or incision and drainage of cavities; third, pneumectomy, or excision of a tuberculous focus, and fourth, obliteration of a cavity by causing collapse of the lung.

I shall briefly give the indications for each plan, with those points of technique already established, and the present status of each procedure as I understand it.

**Aspiration.**—The treatment of all septic cavities in all parts of the body by aspiration and medication has been a disappointment as a rule. Even the permanent retention of a trocar for drainage has not been adequate, and disinfection by antiseptics, when not supplemented by drainage of a most radical type, usually fails. Consequently, we are not surprised to learn that this method, when applied to pulmonary cavities, is unsatisfactory. Mechanically it is easy and the practice safe enough at the moment, so far as the trocar is concerned, but it is drainage that does not drain, and the improvement from the medication is so slight as to condemn the method.

**Pneumonotomy.**—This method of treating a tuberculous cavity comes to our attention with a certain prestige, for it is reasonably successful in cases of simple abscess, in gangrene, and in bronchietatic cavities. In abscess cases, from fifty to seventy per cent. of cures are alleged. In patients with gangrene of the lung operated upon local skin anesthesia, there is a list of ninety-six cases with fifty-four complete cures and three recoveries with fistula. Attempts to drain a dilated bronchial cavity are less successful as regards ultimate results. In phthisis cases the operation is indicated only when the general tuberculous involvement of lung tissue is at the minimum, and the patient is suffering from the secondary septic symptoms of an easily recognized cavity. When relieved of the sepsis, it is hoped that the tuberculous involvement will reach a natural cure. In practice it is found that there is a prompt relief of the fever, the profuse expectoration, and the cough, and, while in a few cases complete cure follows, the majority of patients at length surrender to the tuberculous infection.

The steps of a pneumonotomy are given as follows: A subperiosteal resection of a rib, a transverse incision of the parietal pleura. If the lung is adherent, an incision is promptly made along the line of an aspirating needle which has located the cavity. If the lung is not adherent, there is some difference of opinion concerning the treatment of the pleural cavity. Sonnenberg would suture the parietal and visceral pleural layers and immediately incise the lung. Tuffier would searify the opposing layers, apply chloride of zinc, place a few retaining sutures, pack with iodoform gauze, and wait for several days for adhesions before incising the lung. Tait, Abrahams, and others assert that the presence or absence of adhesions is a matter of little importance, and advise a temporary packing off of the pleural cavity and an immediate incision of the lung. They believe that adhesions will form before the discharge infects the pleura.

The lung incision is made with the cautery if the lung tissue is soft and inflamed; but if it is hard, the knife is safe. It is agreed by all writers that irrigation is not admissible. At most the cavity should be sponged out. It is usually stated that an iodoform-gauze drain is better than a tube. Tuffier uses a tube. Fowler, in an article on intrathoracic tuberculosis, calls attention to the fact that the lung is not sensitive, and no anesthesia is required after the resection of the rib. This is important if one operates in two stages when adhesions are absent. Care must be taken on the operating table that the sound lung is at a higher level than the cavity, otherwise the manipulations may force the cavity contents into the main bronchi with disastrous results.

**Pneumonectomy, or Excision of a Tuberculous Focus.**—While part or all of a lung has frequently been removed from the lower animals with complete success, when applied to man it too often fails. For traumatism and for tumor it is usually fatal. A small portion of a tuberculous lung has several times been removed with a cautery, and the patient has lived only to suffer from other foci. If several ribs are resected and with the pleura attached are turned back, so that there is plenty of room to work carefully, it is probable that better results can be obtained in various lesions; but as
He reports a few cases which are satisfactory so far as they go, but which are not sufficient, either in number or in time elapsed, to prove the practical value of his plan. It is my impression that there is merit in it, and I have been surprised not to see more reports from him or from other sources that would be conclusive regarding its utility.

**MASTOIDITIS: THE IMPORTANCE OF EARLY SURGICAL TREATMENT.**

**By James Francis McCaw, M.D., Watertown, N.Y.**

Oculist, Aesthetic, and Rhino-laryngologist to City Hospital and Jefferson County Orphan Asylum, Etc.

If the busy general practitioner could review the aural literature, he would, I am sure, be surprised at the frequency of mastoiditis and its intracranial complications.

When we take into account the very high mortality of intracranial lesions, either with or without surgical interference, we at once realize the great importance of the early institution of proper measures for their relief, for in this way we shall not infrequently save a life that otherwise would be sacrificed; whereas, if "dilly-dally" methods are adopted, a very large percentage of our patients will die from either epidural abscess, lateral sinus thrombosis, cerebral or cerebellar abscess, or that most dreaded of all complications, purulent meningitis.

The importance of mastoiditis as bearing not only upon the preservation of the function of one of the organs of special sense but also upon the life of our patients make the question of what to do and when to do it worthy of our most careful consideration.

There are few diseases which the family physician is called upon to treat in which the responsibility for prompt and proper advice is so heavy as in mastoid involvement. He being usually the first professional consultant, the well-being of his patient depends upon his ability to differentiate between the number of pathological processes that might occur in this region. I saw it stated not long since that "the physician who fully realizes the dangers to which aural diseases, both acute and chronic, may lead, is more apt to give proper advice than one who is accustomed to regard them as troublesome sequelae beneath his dignity to notice." I should like to emphasize this statement, for I have been surprised oftentimes, when patients have presented themselves for examination, to learn that no attempt had ever been made to find out the true condition of the middle ear and its accessory sinuses. I refer more particularly to the chronic otorrhoeas. If in this paper I succeed in impressing upon you as family physicians the importance of this knowledge, and lay down a few short rules to aid you in dealing with this class of cases, I shall consider that it has served my purpose.

* Read before the City Medical Society, November 14, 1899.
Mastoiditis as a primary disease rarely occurs, but usually follows one of two conditions, viz., acute and chronic suppurations of the middle ear, regardless of the aetiologic factor, but is manifestly more common where the infection is of a very virulent nature—as in suppurations following scarlet fever, diphtheria, epidemic influenza, and measles—than where it is of a milder type, as in ordinary head colds.

Clinical experience teaches us that in the more virulent infections there is a very rapid destruction of the lining membrane of the middle ear, and later necrosis of the ossicular chain and bony walls. In these cases, when dealt with promptly, paracentesis of the drum, leeches, ice bag or cold cloth, free catharsis, and thorough cleansing may avert a threatened mastoid involvement, but they must not be relied upon where the disease is firmly established, for nothing short of opening the mastoid cells is in my opinion justifiable. This is doubly true in cases following chronic otorrhea. Here the life of the patient is hanging in the balance, and there is no good reason to suppose that the pus will find its way out externally; whereas, if we consider the very close proximity of these cavities to the cranial cavity, being separated by only thin bony partitions, we see that everything is in favor of an extension to the intracranial contents, and as a matter of fact we find this is true in from ninety to ninety-five per cent. of neglected cases.

The writer is aware that there are cases that sometimes end in recovery without operative interference, but the few that one sees in an ordinary experience should have very little weight in answering the question as to whether in a given case the patient will recover without radical measures. The danger is not in operating, but in waiting until the disease is beyond our control.

In acute cases the question of when to interfere surgically or how far we may go in the application of milder therapeutic measures before our patient passes the border line of danger, is often very difficult to answer. Professor Schwartz, who was the first to advocate the thorough opening of the mastoid cells and has placed the operation upon a sound basis, says that if in acute cases the pain, fever, and swelling do not subside within eight days the mastoid cells should be freely opened. This is not an invariable rule, and each case must be judged individually. In doubtful cases there is one sign made out by otoscopic examination which, if present, is regarded as indicative of pus in the mastoid cells. I refer to the sagging of the postero-superior cutaneous covering of the external auditory meatus close to the membrana tympani, which usually drags with it also the membrana flaccida. I have become so thoroughly convinced of the value and importance of this sign that I feel justified in recommending operative interference in all cases where it appears.

Gorham Bacon, in the Medical News, June 19, 1897, in speaking of acute inflammation, says: "The operator should not wait for oedema and redness behind the ear, as valuable time may be lost in so doing. Bulging out of Shrapnell's membrane, with drooping of the posterior and upper cutaneous lining of the external meatus, are, in the author's opinion, absolute symptoms of mastoid involvement, and he believes that in such cases the mastoid cells should always be perforated."

Dench, in his book upon Diseases of the Ear, p. 446, says: "I have never met with an instance in which, when this sign was present, operation upon the mastoid did not reveal the presence of pus."

There are others who advocate a more conservative plan of treatment, but they are greatly in the minority, and the tendency is toward more radical measures. From my clinical experience and the literature of the subject, I am forced to the conclusion that where there is undoubted mastoid involvement the only safety lies in early operation, before the patient passes the border line of safety into the dangerous grounds of meningeal and cerebral complications.

In answer to the question, When shall we interfere surgically? I should say, Apply that invariable rule of surgery that wherever there is pus it should be evacuated. My own observation, well borne out by the almost universal opinion of the best authorities, proves that sagging of the postero-superior canal wall is indicative of the presence of pus. If that is true, the natural deduction follows that when this condition is present it calls for surgical interference in the patient's behalf.

In mastoiditis following the chronic otorrhcea there is no ground for discussion. The only thing left for us to do is to deal with it radically and at the very earliest moment, for it is the danger signal, and if unheeded is sure to lead to disastrous results. For a physician to stand by and wait for the catastrophe of which he has been forewarned is little short of criminal negligence.

The seriousness of these cases is increased by the difficulty in the matter of adequate drainage through the tympanum and the necrosis of the bony walls which is usually present. The gravity of the affection is not always commensurate with the symptoms, for it is in this particular class of cases that we sometimes find the most destructive changes taking place, changes which are threatening the very life of our patient, with few signs to guide us. For this reason it is advisable that all chronic otorrhcea should receive most careful attention and the case be dealt with radically so soon as there is any indication of mastoid infiltration or pus formation outside the tympanic cavity.

The question of whether we shall select the Schwartz, or simple, operation, as it is called, or proceed more boldly into the Stacke, or radical, operation in a given case is of little consequence, as the first step in each is the same, and the simple can be converted into the more radical if we find the conditions warrant it.

In general, however, the simple operation is usually all that is necessary in acute cases, while the radical is
reserved for cases following chronic suppuration of the middle ear.

Conclusions.

1. In threatened mastoid involvement and in the mild acute cases the conservative plan of treatment should be first tried for at most a week or ten days, unless dangerous symptoms arise.

2. Operative interference should be instituted (a) in acute cases where there is sagging of the postero-superior canal wall; (b) where the infection is of a virulent nature; and (c) in all cases complicating chronic otitis media.

35 Washington Street.

HEROIN IN AFFECTIONS OF THE RESPIRATORY ORGANS.

By HENRY D. FULTON, M.D.,
PITTSBURGH, PA.

The new medicinal agent heroin, a derivative of morphine, a favorable report of which was made by Dr. Morris Manges, of New York, in the New York Medical Journal, November 26, 1898, promises to be a remedy of real value and, indeed, a very important addition to our therapeutic resources, even if further study and investigation do not widen its field of usefulness beyond the clinical results so far obtained.

The use of heroin in the hands of the writer covers a period of five winter and spring months, when diseases of the respiratory organs are most common in western Pennsylvania, and the diseases studied with reference to its medicinal action comprise cases of simple bronchitis, bronchitis associated with measles, the bronchitis of la grippe, chronic bronchial catarrh, acute pneumonia, and phthisis. Some of the remedy was obtained in December, 1898, while the epidemic of la grippe was at its worst, and the effects of the agent as a cough-relieving remedy in this disease were prompt and definite; the degree of comfort afforded the patient was in marked contrast to that usually derived from the ordinary remedies. In those cases in which the patient is harassed by almost incessant cough, or by severe paroxysms occurring in the night, so greatly interfering with the rest and comfort of the subject and leading to an exhausted condition on the following day, its good effects were especially noticeable. In la grippe the range of its usefulness is limited apparently to the allaying of cough and it does not otherwise influence the course or duration of the disease. The remedy was exhibited in this affection, in simple and in complicated cases, with the one uniform result of securing relief from the distressing symptom of cough by lessening the troublesome bronchial irritation which usually exists. The administration of heroin in phthisis at any stage is followed by the most satisfactory results in the way of securing freedom from cough and thereby promoting rest at night.

The first case in which this remedy was tried was one of advanced pulmonary disease with laryngeal involvement. The patient, extremely emaciated and weak, suffered greatly from coughing, especially at night, and scarcely any relief had been afforded by intralaryngeal applications, inhalations, or by sleep-producing remedies.

The patient stated that he had not had a comfortable night for months. Heroin in one-sixteenth-grain doses was ordered every three hours.

The administration of the drug was begun early in the afternoon and continued every three hours until nine o’clock in the evening. The cough was greatly relieved and a comfortable night was had, the first for a long time. The patient succumbed to the disease in about two months, securing sleep at night during that period and marked relief from cough. The writer was much interested on his second visit to this patient to note the appearance of comfort instead of his former wretched expression of suffering. His extravagant words of praise for the remedy through which he had obtained such unexpected help, his surprise that he could possibly have had a night free from his usual troublesome cough, and his evident happiness and gratitude over the changed state of affairs were fully justified by the subsequent action of the drug, which was continued without appreciably increasing the dosage while he lived. In the second case the writer forwarded some heroin to a young man, a former patient, then in California on account of gradually progressing phthisis. He had been taking codeine to relieve cough, but his sleep was considerably interfered with, and he sometimes had very bad nights with the usual depression and exhaustion on the following day. After I began the use of this remedy his sleep was uniformly good and some general improvement in his condition ensued on account of his securing uninterrupted rest at night. The results were so prompt and apparent that he sent back at once for a quantity of heroin, and has continued its use since early in last January up to the present time. This patient, after seven months’ use of the drug, still relies upon it to relieve his cough, and has only slightly increased the doses necessary to obtain the desired results. It does not in his case cause constipation, and has produced none of the evil effects that accompany the prolonged administration of morphine.

In two other cases of phthisis which have come under the writer’s observation, both in young women far advanced in the disease, heroin in one-twelfth-grain doses, given at 3, 6, and 9 p.m. daily, controlled the cough sufficiently to permit of sleep at night, and this with unvarying certainty.

While heroin is a veritable boon to the consumptive as a palliative in cough, it has a wide range of usefulness in both acute and chronic forms of bronchitis.

In a large series of these cases during the last winter, the remedy was employed with great satisfaction. In
the acute bronchitis of children its employment is followed by prompt amelioration of cough and apparently moderates the severity of the attack. In chronic bronchitis catarrh it seems to have a positive curative value and marked improvement has been observed in a number of long-standing cases.

In a child, six years old, subject to recurring attacks of bronchitis in cold, damp weather, and having been ill during the greater part of the winter, the use of heroin in one-thirty-second-grain doses every four hours, increased in a few days to a sixteenth grain at the same intervals, was followed by remarkable improvement in the cough, which had been paroxysmal in character and very distressing to the little patient. In measles, when the bronchial irritation is a prominent symptom, the writer has found nothing else so serviceable as heroin in suitable doses to tranquilize the persistent cough. A solution of heroin for hypodermic administration may be prepared by the addition of a small amount of acetic acid, and will be found equally efficacious as morphine and less objectionable in cases of spasmodic asthma. By a previous knowledge of the patient in most of the cases in which heroin was employed with such marked advantage, it was not difficult to estimate the share which this agent had in bringing about improvement or recovery. Maximum doses of heroin produce gastric disturbance similar to that following the exhibition of morphine, but in a lesser degree, and its desired effects can usually be obtained short of causing any derangement of the digestive functions.

DIET IN TYPHOID FEVER.*

By EDWARD SPEIDEL, M.D.,
Adjunct Professor of Obstetrics, Gynecology, and Abdominal Surgery, Hospital College of Medicine, Louisville, Ky.

Possibly the most important thing to learn in dieting a typhoid patient is the proper restriction of the amount and variety of foods allowed him. The ideal treatment of typhoid now depends upon a primary evacuation of the gastro-intestinal tract and a total abstinence from all food for five to six days in order to keep the alimentary canal in an aseptic condition as possible, and to furnish no pabulum for the development of the typhoid bacillus. It has been demonstrated by the public performances of Tanner and other professional fasters that the healthy human being can subsist upon water alone for at least forty days, and the diet in a condition like that of typhoid fever, in which there is for a period at least a constant elevation of temperature and consequent loss of water by the tissues, should be calculated to supply this waste. Consequently, the most important food in typhoid is water, and it should be administered at regular intervals during the waking hours, without waiting for the patient to call for it. Especially during the first two weeks this is important, and the amount given is, of course, regulated by the height of the fever. As the typhoid infection is often traceable to the water supply, the water should be sterilized by boiling and subsequent cooling by placing bottles of it in the refrigerator rather than ice in the water itself. The flatness of water that has been boiled may be removed by shaking it in bottles half filled before serving, so that the air expelled from the water by boiling may be reabsorbed.

From the onset of the disease a daily rectal irrigation with a half gallon of normal saline solution will answer the purpose first of all of cleansing the lower bowel, and, from the fact that a large portion of the fluid is retained by the intestines, of furnishing not only a large quantity of water to the tissues in this way, but also a definite quantity of chloride of sodium, so necessary to the animal economy. Under circumstances in which the patient can not swallow the requisite amount of water, it may be given entirely by rectal enemata, and when administered with the fountain syringe and soft rubber catheter can be used without harm to the patient in ordinary cases.

In cases of intestinal hemorrhage this method can, of course, not be used, and then the water must be administered interstitially, and I present here a simple portable apparatus with which such injections can be given with ease and rapidity. It consists simply of a four-ounce glass funnel, two feet of rubber tubing, and an aspirator needle. The various parts are sterilized and put together, the funnel filled with the saline solution, the liquid allowed to flow in order to expel the air from the tubes, and the needle then inserted under the skin, either in the region below and between the scapulae or anteriorly at the sides of the right or left hypochondriac region. A pint of solution will be readily absorbed by the tissues in from fifteen to thirty minutes, and I have on several occasions given half a gallon of normal saline solution in this manner in the course of a few hours.

In extreme cases it may be necessary to administer the water intravenously, and then the same simple apparatus will answer all purposes. The needle is inserted into the median basilic vein with the aseptic precautions that are usual under such circumstances.

It is in the administration of other foods that we are apt to err upon the wrong side by giving more than is needed for the comfort and necessities of our patient. Very rarely do our typhoid patients die of starvation, and the very marked cardiac depression in this disease is not due to the loss of vital power in consequence of an insufficient amount of food. It is due to the septic fever caused by the absorption of typhoid pomaines, often aggravated by the absorption of toxic products due to the ingestion of too much food and the decomposition of such food in the enfeebled gastro-intestinal
canal. The delirium and tympanitis complicating the
disease may generally be ascribed to an error in this
direction. The amount of food given should be in
proportion to the digestive capacity of the patient as
evidenced by the absence of undigested food in the
stools and by the temperature, a patient with a very
high fever being practically in no condition whatever
to digest food.

The ideal food in typhoid is buttermilk, and I have
observed that patients who subsist upon it exclusively
during the febrile stage of the disease get along smooth-
ly and without complications. No special precautions
seem to be necessary in its use; it should, of course, be
obtained fresh each day.

Next in order then is sweet milk, and as it contains
all the constituents needed to supply the tissues it ful-
fills all purposes. The only drawback to its continued
use is the fact that many patients have a distaste for it,
and attempts must then be made to present it in various
palatable forms.

As the milk supply is often the cause of typhoid,
some care must be used in its administration. Boiling
destroy's the vital principles of the milk and makes it
less palatable, and should not be resorted to if other
means will answer. Dr. Seibert, of New York, has
demonstrated that when milk is filtered through absorb-
ent cotton, nine tenths of the bacteria, together with all
the foreign particles, are removed from it, and in the
majority of cases such simple filtration should answer.
If necessary, pasteurization or sterilization may be
resorted to.

Milk can be rendered more digestible by mixing
with an equal quantity of water and then aerating it.
A half pint of milk and of water are placed in a quart
bottle and shaken very thoroughly just before pouring
out the quantity to be administered to the patient.
This mixture can then be improved upon by the addi-
tion of a teaspoonful of the white of egg, a teaspoonful
of sugar, and a pinch of salt, making a milk shake
which will hold the froth and present a very appetizing
appearance to the patient. By the addition of a tea-
spoonful of the various fruit juices, especially pine-
apple and cherry, this can be varied again. In cold
weather the addition of a teaspoonful of clam juice to
the diluted milk, salted to taste and served hot, will
be acceptable. Milk mixed with an equal quantity of
coffee or tea can be given twice a day and will answer a
double purpose, the caffeine and theine contained in
them acting as heart stimulants, a quality very desir-
able in the early stage of the disease. A very satisfac-
tory method of administering milk was communicated
to me by Dr. Fallis, of this city, only a short time ago.
It is in the form of a peptonized ice cream, made by
taking a measureful of peptogenic milk powder, adding
to half a pint of milk half a pint of water and four
tablespoonfuls of cream, and heating to the boiling
point, according to directions accompanying the pepto-
genic milk powder. The mixture is then transferred
to an ice-cream freezer and frozen in the usual way.
A cupful of this served at regular feeding hours will
prove very acceptable to most patients, especially as it
bears some semblance to solid food and may be eaten
with a spoon.

A teaspoonful of extract of malt, heated with half
a pint of milk and then diluted with an equal quantity
of water, forms another easily digestible mixture.

When milk is absolutely refused, it will be found
that the patient can be sustained during the entire
febrile stage of the disease upon unfermented grape
juice given in wine-glass doses every three hours.

When the temperature reaches normal in the morn-
ing then an addition may be made to the diet, either
by the substitution for one of the feedings of strained
oyster or clam broth or by the various beef preparations.
Books on diet contain a number of formulas for the
preparation of beef tea; but if the patient can be trusted
I allow him to chew pieces of broiled steak, instructing
him not to swallow the fibre after the juice is absorbed.
The tougher the steak, the more satisfaction will the
patient get out of it.

At this time the patient should be allowed the use
of chewing gum for a short period several times a day.
The satisfaction of again using the muscles of mastication
is one that only he who has been deprived of their
use for some time, as in this disease, can appreciate.
Liquid beef peptonoids, Moquera's beef jelly, and Valen-
tine's meat juice will fill the indications when fresh
beef can not be had conveniently.

The gradual change from the liquid to the solid
diet puzzles the physician perhaps more than anything
else. The difficulty will be solved if the gelatin prep-
ations are used, gelatin with wine or pineapple juice,
also the various preparations of tapioca, which is con-
verted into a smooth, transparent jelly by a process
of boiling and subsequent cooling. Diluted milk with a
tea-spoonful of sugar, a pinch of salt, and one or two
tablespoonfuls of whisky added to it will make an ex-
cellent nightcap at this period.

Soft boiled eggs are, of course, indicated and are
best prepared by heating an egg with a quart of cold
water to the boiling point.

The yolk of an egg beaten up with diluted milk, with
or without whisky, will lend variety to the diet. Oyster
and clam broth in winter and tomato soup in summer
are in order. The patient will crave bread by this time,
and a palatable and safe way of giving it is in the form
of bread jelly, made by covering a thick slice of home-
made bread with water, allowing to stand an hour,
pouring off the excess of water, adding milk, heating to
the boiling point, sweetening to taste, and serving
cold.

After this, of course, the various meat soups—beef,
mutton, or chicken—with well-boiled rice, barley, sago,
or tapioca, and finally mashed potatoes are in order;
and then, as a general thing, the patient can consume the normal diet.

In cases in which digestion is so enfeebled that the ordinary foods cannot be administered, other means must be resorted to.

It may astonish many to learn that the raw yolk of an egg, salted and floated on two tablespoonfuls of sherry wine, will be retained and absorbed by the weakest stomach, and such a dose repeated two or three times a day will tide a patient over an emergency. A half to a pint of coffee injected into the rectum in such instances will have a stimulating effect very valuable to the patient.

It may finally be necessary to resort to predigested foods, and then the various modes of peptonizing food may be employed, or the prepared foods may be used, such as trophonine, beef peptonoids, panopeptone, somatose, etc.

I have scarcely referred to the use of alcoholic stimulants in connection with the dietary because it is now generally conceded that alcohol is not a food, and its property as a heart stimulant can be better filled by the judicious use of strychnine.

In ordinary cases of typhoid fever and with many patients a very simple dietary will answer, but when complications occur and the patient rejects the ordinary routine, then the physician is often at his wits' end to supply his patient's wants without injuring his prospects of recovery, and under such circumstances the suggestions outlined in this paper may be of service.

EXAMINATIONS OF THE URINE IN EPILEPSY.*

By EDWIN G. KLEIN, M.D.,
MEDICAL INTERNE, WILLARD STATE HOSPITAL, WILLARD, N. Y.

The subject of the urine in the insane was considered in a general way in a paper read before this society last January. Since then examinations have been made with the urine of epileptics, with a special reference to the presence of albumin and glucose closely following a seizure, and during an interval of freedom from seizures, and under a special diet of starchy and saccharine food stuffs. In the first of these, the urine of twenty-three patients—twelve women and eleven men—was collected as soon after a seizure as possible. The time of collection varied from ten minutes to five hours, the average being about an hour and a half. Contrary to the statements in most text-books, very little polyuria was observed. The specific gravity ranged from 1.007 to 1.026, the average being 1.020. The color varied from a pale straw to amber, mostly the latter. The reaction was acid in all but two cases. In the latter it was alkaline and had been collected during what Haig terms the "alkaline tide." Albumin was present in faint traces in fifteen of the twenty-three cases.

Four tests for albumin were used—namely, the boiling test, Heller's test, Roberts' nitric magnesnum fluid, and Spiegler's reagent. In only one case (a case of chronic nephritis) was albumin present in sufficient quantity to be detected by the boiling and Heller's tests. Eight responded to Roberts' test, and all fifteen gave distinct results with Spiegler's reagent.

Finding albumin (not albumose) so frequently with the latter reagent occasioned some doubt as to the accuracy of the test. But later the same reagent was applied to the urine of the same patients during a comparatively long interval between seizures, and only three of the total number gave positive results. This, in addition to like results obtained with normal urines, seemed sufficient proof of the reliability of the reagent and the findings obtained therewith. It would seem that the presence of so small an amount of albumin in the urine after an epileptic paroxysm would be of little significance, for it is well known that traces of albumin, even up to 0.1 per cent., may be found in the urine after moderate bicycle riding, cold baths, etc. By some this is considered physiological, but others are inclined to believe with Simon, who says: "The more closely the subject of so-called physiological albuminuria—following severe muscular exercise, cold baths, mental labor, severe emotions, digestion, etc.—is studied, the more improbable does its physiologic nature appear, and a more detailed study of the metabolic processes, it may be confidently asserted, will ultimately lead to the conclusion that the presence of albuminuria (serum albumin) in every case is a pathologic phenomenon" (1).

A. Robin has a strong conviction that these functional and secondary albuminurias are apt to persist, and to result in actual lesions of the kidney and the development of Bright's disease (2).

Stephan thinks that in many cases functional albuminuria is due to toxic causes, which may be introduced into the body, or may be produced by digestive or metabolic disturbances within the body, and that other cases may be reflex, vasmotor, or trophic disturbances (3).

Whether the transitory albuminuria following epileptic seizures is due to a toxic origin or to increased blood pressure, or is produced by digestive or metabolic disturbances, still remains to be demonstrated. In the case of chronic nephritis mentioned, it appeared (if one can judge from three observations) that the albumin was increased shortly after a convulsion.

This patient was admitted fifteen years ago, and, according to the case notes, he was in very excellent physical condition when admitted, considering other facts found in his history; and, judging from his present condition, it is fair to assume that the nephritis is of recent origin, and is without any obvious cause.

* Read before the Willard State Hospital Medical Society, September 20, 1899.
The question arises, Is this case one which began as a functional albuminuria? Albumose was found in three of the above-mentioned number. In one patient it was found three times after a convolution. The biuret test was employed. It is not believed that the presence of albumose in the urine of these cases has any direct relationship to the convulsions, but rather it may be regarded as evidence of defective metabolism. Chlorides were tested volumetrically, and were found to be in excess after a convolution in fourteen of twenty-one patients examined. In six out of ten examined during an interval between seizures, the chlorides were present in normal quantity, while in the four others they were decreased.

Boline has reached the conclusion that retention of chlorides in the organism, if not the only cause for uremic and comatose conditions, is nevertheless the one principally concerned (4). Glucose was not found in any of these cases. The tests applied were Nylander's and the Worm-Müller modification of Fehling's test. In every case the urine was subjected to a preliminary filtration through animal charcoal. As this method was adopted in all the examinations included in this paper, and as some doubt exists as to the advisability of using animal charcoal for this purpose, it might be well to add a few words in regard to it.

Sir W. Roberts strongly advocates preliminary filtration of the urine through animal charcoal, and gives his reason that the urine is thus freed from uric acid and urates, as well as from the coloring matter, whereby the urine is brought to a peculiarly favorable condition for giving a clear and definite response to the copper tests (5). On the other hand, the observations of Secgan and Mark McDonald seem to show that "filtration through animal charcoal leads to some loss of sugar, the charcoal retaining it so firmly that even thorough washing will not remove all of it." (6).

The writer concluded to follow the recommendations of Sir W. Roberts after submitting the matter to a practical test—viz., a small quantity of glucose was added to a normal urine. A portion of the mixture was examined for glucose without previous filtration through animal charcoal, while the second portion was examined after filtration, and it was found that not only was the reaction for glucose more clear and unquestioned in the filtered portion, but also, after further dilution, gave the reaction longer. Further, by thus filtering the urine of the cases in question, it is believed that the difficulty pointed out by Dr. McDonald was avoided—namely, "the difficulty in deciding whether the urine contains a little sugar, or whether it is simply that its normal reducing substances are present in excessive quantity." (7). For it was found that in the present examinations many of the urines gave very confusing reactions prior to filtration, and it seems that, although a slight loss of glucose may be occasioned by filtering the urine through animal charcoal, the fact of thus eliminating a large source for error is of a decided advantage. It is true that the use of the phenyl-hydrazin test would not have necessitated filtration, and that therefore the question of loss of glucose would have been avoided. But the Worm-Müller test was preferred because of its greater delicacy, and because of its simplicity as compared to the former. The non-finding of glucose in these cases is but in accord with the observations of Simon. Dr. Simon obtained only negative results in a large number of cases of epilepsy with the urines voided the first few hours following the seizure.

As already stated, the urines of the same patients were examined during a comparatively long interval between seizures.

The same methods and tests were applied as in the first, and, excepting the results as already stated, the urines, so far as examined, did not seem to differ from normal urine. In the third series, fourteen patients were put on a very liberal starchy and saccharine diet for from two to four days. This diet consisted of rich cakes, cornstarch puddings, preserves, cereals of various kinds, cocoa, etc. It is estimated that in this diet each patient consumed from five to seven ounces of cane sugar daily. The urine examined was obtained between one and two hours after every third meal.

In ten cases, where only six meals were taken, no glucose was found. Two cases did not show glycosuria after nine meals, while the remaining two showed traces of glucose after the twelfth meal. By obtaining the latter results, it was thought that by persisting in the diet the degree of glycosuria might increase proportionately. Accordingly, six other patients were selected and were given the diet for one week. For convenience I will number these patients from one to six inclusive. After the first day no change in the urine was noticed. At the end of the second day, the urine of No. 1 gave a slow but decided greenish reaction, and after twenty-four hours a slight deposit of the suboxide of copper was found. After the ninth meal Nos. 1 and 2 showed a quick greenish reaction, No. 3 being very slow and faint. After twenty-four hours a small deposit of the suboxide of copper was found in Nos. 1 and 2. In No. 3 the deposit was very slight. From then to the twenty-first meal, beyond an occasional greenish reaction, no further change was observed in these cases. In No. 4 no reaction for glucose was noted until after the twelfth and fifteenth meals, and none thereafter. In these, as in the former, the reactions were slow. No. 5 showed only a slight reaction after the fifteenth meal, none after the eighteenth, and a decided greenish-yellow reaction (no deposit) after the twenty-first meal; and No. 6, beyond an occasional greenish reaction, showed no glycosuria throughout. All the foregoing results were obtained with the Worm-Müller test. Nylander's test was also employed, but, as expected, it proved too
coarse. Fehling's test solution, as ordinarily prepared and used, was employed in the urines in which the Worm-Müller test gave positive reactions, but, excepting in one case, the solution did not even change color from the characteristic blue. Although the glycosuria in these cases was not very marked, it is believed that the results as found were greater than they would be in normal people under like conditions. For it is quite clearly established that prolonged, increased carbohydrate diet causes little or no increase of sugar elimination in normal cases. It is also thought that, were it not for the well-known fact that digestion and absorption are slow in epileptics, even more glucose would have been found in these cases.

Owing to the inability of the writer to find any literature or statistics on the subject of diet and its influence on the urine of epileptics, a comparison of these results will have to be omitted. One reference was found on the relationship of diabetes mellitus and epilepsy. This was by Dr. Ebstein. In referring to several cases in his experience, he says that the relation may be one of pure association, the epilepsy may be due to diabetes mellitus, or the diabetes mellitus may be the result of the epilepsy (8). Although a transient glycosuria can be readily induced, and may often be present in epileptics, as in fact in most all nervous conditions, it is not believed that it plays an important rôle in the production of true diabetes mellitus, for it is well known that cases of true diabetes mellitus are very rarely found in insanity hospitals. The combined number of seizures during the week of the diet was twelve. Eight of these occurred within five hours of collection of the urine, and the remaining four between eight and twenty hours. In the first albumin was noted four times, albumose three times (twice in one patient), and chlorides were in excess in four. In the remaining four albumin was found but once, albumose once (same patient as above), and no appreciable change in the amount of the chlorides was noticed.

The Northwestern Medical and Surgical Society.—At the recent annual meeting officers were elected as follows: President, Dr. Robert A. Murray; vice-president, Dr. Frank Grauer; treasurer, Dr. Robert H. Greene; secretary, Dr. S. Henry Dessau.

Therapeutical Notes.

For the Stomatitis of Gripp.—Presse médicale for August 19th recommends the following:
B Laetic acid 3 1/2 grains; Essence of mint 10 drops; Water 3,750 grains.
M. The mouth may be washed twice daily with this lotion. If there is suppurating in the tonsillar crypts the following may be applied:
B Salicylic acid 1/4 to 15 grains; Alcohol q. s. to dissolve; Glycerin 900 grains; Water 150 “
M.

Iodide of Potassium in Enemata.—Journal de médecine de Paris for December 24th quotes from Gazette des hôpitaux, June 1st, the assertion that when iodide of potassium is not well tolerated by the stomach and is consequently administered in an enema, too great a quantity of fluid is commonly used. M. Kirstein recommends the employment of a syringe furnished with a caoutchouc nozzle. Two coffeespoons (about a hundred and fifty minims) of the following solution should be injected into the rectum three times daily:
B Distilled water 3,000 grains; Iodide of potassium 150 “
M.
To accustom the rectum to the drug it is suggested that less strong doses should be used at first.

An Ointment for Pruritus.—Progres médical for September 23d attributes the following formula to Leredde:
B Methyl salicylate 2 parts; Zinc oxide 1 each 20 “
Vaseline
M.

For Nervous Maladies and Mental Depression.—According to the Journal de médecine de Paris for September 10th, Robin recommends:
B Glycerophosphate of lime, from 3 to 6 grains; Powdered nux vomica 1/6 to 1/8 of a grain.
M. For one dose.
Kahane prescribes:
B Glycerophosphate of sodium 375 grains; Distilled water 750 “
Orange-flower water 1 of each. 450 “
Syrup of orange peel
M. One coffeespoonful three times a day.

The Inunction of Salicylic Acid.—The Medical News for December 16th says that salicylic acid, if mixed with an oily vehicle, is quickly absorbed. It may be prescribed thus in connection with its internal administration for rheumatism. Oil of wintergreen may be used in place of it with advantage.
B Salicylic acid 2/3 drachms; Alcohol 1/4 ounce; Castor oil 3 ounces.
M. S.: Rub into the affected part, covering first with an impervious material, then with flannel or cotton wool.

A WEEKLY REVIEW OF MEDICINE.  

NEW YORK, SATURDAY, DECEMBER 30, 1899.

RECTAL MASSAGE FOR COCCYGODYNIA.

There are probably various morbid conditions that may account for the painful affection known as coccygodynia, a term, by the way, not wholly satisfactory, since the pain is not always referred to the coccyx itself, is not invariably aggravated by movements of that bone, and is not generally cured by its removal. Dr. H. Rose, of Hamburg (Centralblatt für Gynäkologie, November 25th), seems to have discovered a previously unrecorded and probably unnoticed cause of the affection, and at the same time the fact that this particular form of coccygodynia may be cured by so simple a procedure as massage executed from within the rectum. He has met with a number of cases in which the pain was increased by pressure upon a tender point situated in the immediate neighborhood of the third or fourth anterior sacral foramen, generally the fourth. In slight cases only this point of tenderness is detected, but in those that are severe there is tenderness also involving a very definite area of small extent. This swelling he attributes to chronic oedema.

In his first case he happened to observe that continued pressure on the tender and swollen spot, associated with gentle friction in a circular direction, caused the puffiness to disappear and at once relieved the pain. It came back after a few hours, but, acting upon the hint he had obtained, he repeated the manoeuvre daily for a time and then at longer intervals until at last even the occurrence of menstruation did not bring back the pain. He has employed this treatment in a number of cases, and invariably with good results. He thinks his success can not have been due to suggestion, for he was careful in all his cases to eliminate that possibility; he would purposely touch some other point than the swollen one, saying to the patient: "Now I am on the sore spot." "No," was the invariable reply, "that is not it." Moreover, massage of any other area was fruitless.

Dr. Rose gives short histories of three of his cases. One of them was in a woman who was under treatment for chronic cystitis and pelvic peritonitis. Five years previously, ten years after the birth of her only child, the coccygodynia had begun with severe pain on sitting down, so that she got into the habit of sitting on one buttock only. At first the pain occurred only in connection with the menstrual flow, but it afterward became more continuous and severer, and was aggravated during defecation and by walking. The second case presented the peculiarity that stooping increased the pain. It was in this instance that the tumid area corresponded in situation to the third anterior sacral foramen. The only noteworthy features about the third case were that the patient had never been pregnant and that the pain was most severe in the anus. All three of the cases were severe.

The trouble in these cases described by Dr. Rose seems to have been coccygeal neuralgia depending on pressure exerted by an oedematous swelling on a sacral nerve at its point of emergence. Its manifestation in the area of distribution of the coccygeal nerve Dr. Rose attributes to the almost invariable communication of that nerve with the last sacral. This form of coccygodynia is favored by any condition that conduces to blood stasis within the pelvis, and after it has been cured by means of massage relapses are chiefly to be guarded against by keeping the bowels free. Of course, inflammatory and congestive pelvic diseases favor the edema to which the neuralgia is attributable, and they should not be neglected, but Dr. Rose has made it plain that independent treatment of the coccygodynia is capable of curing it while yet such diseases persist. The author does not affirm that massage is the only remedy, but, as he is quite justified in remarking, it is a valuable addition to our resources for the relief of a very painful condition.

THE ORIGIN OF SEX.

The literature of the problem of sex production is increased by some Notes on the Origin of Sex published in the Intercolonial Medical Journal of Australasia for October 20th. The author, Dr. Arthur Frederick Davenport, at least gives evidence enough of his capacity to justify attention being drawn to his views; for his obstetrical experience seems to have been considerable, the period over which his researches have extended amounts to sixteen years, his investigations have been supported by experiment, and he appears, moreover, to have thoroughly acquainted himself with what had already been done by others in the subject, thus obviating a not uncommon cause of failure among aspiring original investigators.

The upshot of Dr. Davenport's investigations is what is known as the "cross heredity of sex"--viz., that the sex of the child is determined at the moment of
conception, and is the opposite to” (that of) “whichever parent is at that moment in relatively the more vigorous health.”

Dr. Davenport shows how he arrived at this conclusion, how he subsequently verified it experimentally, and finally how it harmonizes with all that appears probable in each of the conflicting theories of other investigators.

It is a pretty generally acknowledged fact that “the ratio of male to female children at birth varies so slightly in different countries and among different races as to almost constitute a law.” The ratio for Europe is placed at about a hundred and six males for a hundred females.

Upon this the author says: “In striking contrast to this average, preserved regardless of environment throughout the human race as a whole, stands out the disproportion between the sexes often observable in individual families,” the cause of which disproportion must exist in the parents.

During twelve months’ residence in the Rotunda Hospital, Dublin, in 1883, the author began his observations among the poorer Irish families in the slums, who, as he says, “marry young, are rarely sterile, and in the matter of procreating their species take no thought for the morrow.” In the majority of such families he found the greatest disparity between the sexes of the children, amounting in some instances to whole families of ten or more of one sex. Yet, out of between four and five hundred families observed, a total of 2,510 children gave males 1,313, females 1,227—a fairly balanced ratio singularly near the estimated 106 to 100.

Thus came to him the question “Why had A. B., aged thirty, car driver, with a wife aged twenty-seven, a family of one girl and six boys, while his neighbor, C. D., aged thirty-three, laborer, with a wife aged twenty-nine, had a family of seven girls?” The continual repetition of this problem led him to the observation that “the family which contained an undue majority of male children possessed also a mother proportionately more vigorous and in better health than her husband, while in the family with an undue majority of female children the father was proportionately superior in vigor and health to his weakly wife. In many families this rule was exceedingly striking; in others, where the sexes were more evenly matched, so also were the parents.” The author defines the term health in this connection as “meaning practically that condition brought about as the resultant of those forces which create in their own a longer or a shorter ‘expectation of life.’”

From this step to the question Would it not be possible, by exalting the mother’s physical vigor or depressing that of the father—or by a combination of the two methods, just enough to produce a marked preponderance of vigor in the mother’s favor—to induce the conception of boys, and vice versa? was an easy transition.

Dr. Davenport essayed to prove it first on animals. He records his first experiment, made in 1886, with a pair of fox terriers which had previously always produced more or less even litters. When he depressed the dog’s health by confinement, low diet, etc., and elevated that of the shut by fresh air, exercise, plentiful feeding, and so forth, prior to the mating, the gestation resulted in a litter of five dog pups. He repeated the process, reversing the conditions of treatment, with the result that the next coupling produced three bitches and one dog. Dr. Davenport’s views in this matter are supported by the practice of a “station” manager in New South Wales, who, when desiring to perpetuate any strain of cattle and requiring to produce a heifer for that purpose, stall-feeds the bull and turns the cow out to grass prior to service, and reverses the treatment if a bull calf is desired.

The author next put his plan into operation in the human family, and records several instances. On the whole he has had forty-five cases in twelve years. In six instances treatment was futile and was not persevered with on account of organic disease, phthisis, cancer, marked chronic nephritis, etc. Of the remaining thirty-nine families all were picked examples for the application of his methods: each family contained an undue proportion of either male or female children, and in every instance he found the same conditions existing in a more or less marked degree—viz., the majority of male children possessed a proportionately more healthy mother, the majority of female children a proportionately more healthy father. The results were thirty-two successes and seven failures; but in four of the failures no pregnancy could be induced, and of the three others the author says that the measures were undertaken in so half-hearted a manner that he was not surprised at failure.

The following is the author’s modus operandi: He first makes a careful examination of both parents with a view to treating and eliminating any habit, disease, functional disorder, or pathological defect that might have any bearing on the health of the weaker parent. Sexual intercourse is next forbidden for one month and both parents are placed under treatment to build up and elevate the health of the previously inferior parent, and to depress the general tone and health of the previously superior. The first object he achieves: a. By a suitable régime of stimulating diet especially adapted to the constitution to be dealt with, and varying, of course, considerably in different cases. b. By insisting on regular
hours for sleep, exercise in the open air, and sunshine.

3. By a course of tonic and stimulating drugs. 4. By means of the many other ways known to all and used for building up the general tone of the system—viz., change of air if necessary, cessation from overstrain in mental or physical work, etc.

The latter object the author attains by 1. Recommending a course of low diet into which non-nitrogenous elements largely enter. 2. By ordering a maximum of sedentary and brain work with a minimum allowance of sleep. 3. By a course of nerve sedatives, bromides, iodides, etc., for the latter half of the month. The month having expired, intercourse is permitted on the third day after the cessation of menstruation. If pregnancy ensues, all further treatment is unnecessary, the author believing that the sex is determined at the instant of conception. The depression of the stronger parent is entirely temporary and disappears on the resumption of the ordinary mode of life.

As to the theories of others, the author points out that Girou's theory, propounded in 1823, that the offspring follows the more vigorous parent, would ultimately result in the establishment of a colony of males. Cross heredity tends, however, to the maintenance of periodically recurring equilibrium. Hofacker's and Sadler's law, promulgated between 1828 and 1830, that "the sex of the child depends upon that of the parent whose age is in excess of that of the other," simply, according to Dr. Davenport's contention, resolves itself into cross heredity, inasmuch as advanced age means, other things being equal, lesser "expectation of life." The well-known fact of the preponderance of male births after a war the author attributes to the exhaustions and anxieties of warfare having depressed the male population and so placed the women in the stronger position, whence they produce male children.

Finally, Schenk stated in 1898 that the urine of women bearing only female children invariably contained a larger or smaller quantity of sugar. On this the author asks, "Is not the glycosuric mother the less healthy parent," and Schenk's rule therefore only one possible factor out of the more general and broader law of cross heredity?

There is undoubtedly a great deal of thoughtful work in Dr. Davenport's paper, and it is of such a character and so plainly set forth that it can be followed up by the great mass of general practitioners and obstetricians in every country. By this means a consensus of facts could soon be obtained sufficiently large to generalize safely upon. There is no mystery enshrouding Dr. Davenport's views, no attempt to confine the practical application of them in his own hands; those facts in themselves render them deserving of careful consideration and experiment, whatever the actual result may be.

**A NEW STUDY OF INDIAN HEMP.**

That most disappointing of drugs, cannabis indica, has repeatedly been made the subject of investigations undertaken for the purposes of ascertaining its precise physiological action and of obtaining a preparation of unvarying strength. One of the most recent has been made by Dr. Walter Ernest Dixon, whose account of it appears in the British Medical Journal for November 11th. More than one baffling element confronts the investigator who would acquire an exact knowledge of hemp as a drug; not only is there no reasonable approach to certainty that any two specimens can be obtained that will prove identical in their action, but the idiosyncrasy of the subject of experiment is displayed in greater prominence than in the case of almost any other drug, as is well shown by the fact that Dr. Dixon found that equal quantities of the same preparation administered to two similar animals of the same weight and under identical conditions, so far as possible, narcotized one of them and had no effect on the other, which required three times the original dose before it showed any toxic effect.

Dr. Dixon believes that hemp, now naturalized in many parts of the world, was originally confined to a relatively small district in southern Siberia, whence it was carried to India, in which country alone it acquires its medicinal properties. These seem to reside in a resinous substance, but this material is apt to be used up in the formation of seeds unless the female flowers are removed from the plant. The variety of the drug with which he experimented was that known as ganja, consisting of the dried flowering tops coated with resin, and he found it most active when employed in the form of fumes from the burning mass taken by inhalation, although the effects did not last so long as those of the drug given by the mouth. The fumes were rendered much less irritating to the throat by passing them through water, but their action was somewhat diminished by that treatment. Dr. Dixon has convinced himself that hemp of different seasons, grown in various places, and prepared in diverse ways contains different amounts of resin, and that the resin varies very widely in its activity. Although the Indian dealers are said to regard the drug, however grown or prepared, as unfit for use if it has been kept two years, Dr. Dixon found a specimen that had been kept for twenty years but little if at all less toxic than the fresh product.

With all its uncertainty of action, Dr. Dixon re-
Center of the severe attending

objection, of the action of cannabis enables him to affirm that it is soothing and stimulating, and that the fumes have a specially valuable effect as a cerebral stimulant. In suitable doses, he adds, it produces no untoward after-effects.

THE PREVENTION OF LIFE-SAVING BY "CHRISTIAN SCIENCE."

A case recorded in the Western Medical Review for December 15th comes, if accurately stated, clearly within the limits of criminality. A professing Christian-Science healer of Fort Dodge, Iowa, undertook the sole charge of the case of a child suffering from post-pharyngeal abscess. The burrowing nature of this disease is well known, and the importance of providing an outlet for the pus is beyond question. This was not done, and the consequence was that the child died from asphyxia. Mr. Lincoln, the healer in question, signed the certificate as the "attending nurse," giving the cause of death as "spasms." Many of the cases where death ensues under Christian-Science treatment are those of incurable disease, concerning which, while it is probable that proper skilled aid would have ameliorated suffering if not prolonged life, it is yet impossible to assert positively that such would have been the case, and still more impossible to state that Christian Science was in any sense a cause of death. But the case now recorded is one in which proper treatment would undoubtedly have saved life, and death was directly due to its being withheld. Although we believe that Iowa is one of the States that have legalized this pestiferous and unscrupulous charlatanry, there should still be a remedy in a firm application of the law of malpractice.

THE COMPULSORY REPORTING OF CONSUMPTION IN MICHIGAN.

We are glad to learn that the test suit lately brought against a well-known Detroit physician to compel him to pay a fine for omitting to report a case of tuberculous disease has failed, though we wish it might have been for some other reason than the failure of the statute to make specific mention of such disease in its enumeration of those that must be reported.

EPIDEMIC ICTERUS WITH PLEIOCHROMIA.

Epidemics of jaundice are not of rare occurrence, but their atiology is not generally made out satisfactorily. Dr. Dignami (Gazzetta degli ospedali e delle cliniche, 1899, No. 1; Centrallblatt für innere Medicin, December 16th) records one which accompanied an epidemic prevalence of typhoid fever and acute gastro-enteritis. The jaundice was accompanied by severe prostration, muscular pains, and moderate fever of short duration. In the severer cases there was painful swelling of the liver and more rarely of the spleen. The term biliary pleiochromia is employed by the author, perhaps on account of the fact that, in spite of the jaundice, the faces preserved their color. He sought in vain for a specific micro-organism, and thinks the impure drinking water may have given unusual activity to the microbes commonly found in the digestive tract.

OPERATIONS ON THE INSANE.

We lately remarked upon the importance of attending to the physical ailments of the insane. Mr. J. Paul Bush, of the Bristol Royal Infirmary, is evidently of our way of thinking. In the September number of the Bristol Medico-chirurgical Journal he relates a number of instances in which operative measures not only fulfilled their physical indications, but were soon followed by recovery from the mental trouble.

THE WOMAN'S MEDICAL JOURNAL.

It is announced that with the beginning of the year 1900 certain changes will be made in the editorial staff of this valuable journal as to render it still more useful than it is at present. We wish it the utmost success, and have no doubt it will achieve it.

THE EFFECTS OF GREAT COLD ON INJURIES BY CRUSHING.

In the popular mind there is great dread of danger in exposing an injured person to cold. Doubtless it intensifies the shock of a severe injury, but it may have some good effect also. Dr. W. A. Potts, of Birmingham (Edinburgh Medical Journal, December), thinks it may aid in keeping wounds aseptic and determine the occurrence of dry instead of moist gangrene. He gives two cases that seem to lend color to this view.

CARBOLIC ACID MISTAKEN FOR BRANDY.

The Pacific Medical Journal for November records the death of a prominent physician of San Pedro from drinking carbolic acid in consequence of a mistake between two phials in his medicine chest, the one containing that drug and the other brandy. It seems almost incredible that any one, let alone a physician, should be able to drink carbolic acid in mistake for brandy without his nose giving him warning ere the error was accomplished. But the fact, at any rate, emphasizes the importance of always keeping poisons apart from other things, and even in a medicine chest an inner closed compartment should separate them from the bulk of comparatively innocuous drugs.

THE SANCTITY OF PROFESSIONAL CONFIDENCE AGAIN.

In our issue for December 23d we had an editorial note on this subject, commenting on the objectionable standpoint taken by the law officers on that subject in Great Britain. A correspondent in the Lancet for December 2d asks the following questions: "B is seeking a divorce from A. I attended A for an illness in 1889. The solicitor who is acting for B and who is cognizant of the disease from which A suffered wishes me to explain in writing the nature of A's illness. I have told him that I consider it my duty to do so only if called
upon by a court of law. Am I right?” To this the 
Lancet replies editorially: “The only possible answer is 
that our correspondent is certainly right.” As the attor-
ergy was not an officer of the law, we think the doctor 
would have been quite justified in ordering him perempto-
torily out of his house, and we do not see that because 
an objectionable law exists which refuses to recognize 
the inviolable sanctity of professional confidence, the 
physician is therefore called upon to give a would-be 
litigious information as to how compliance with it may 
be enforced.

MR. TAYLOR’S ARTICLES ON THE LAW IN ITS 
RELATION TO PHYSICIANS.

In last week’s issue we printed the concluding arti-
cle of Mr. Arthur N. Taylor’s valuable and interesting 
series. We have heard from many of our readers in 
regard to this articles, and they have invariably com-
mended them. We are glad to be able to announce that 
they will soon appear in book form.

ITEMS.

Infectious Diseases in New York.—We are indebted 
to the Sanitary Bureau of the Health Department for 
the following statement of cases and deaths reported 
for the two weeks ending December 23, 1899:

The Senate Committee on the District of Columbia. 
—In last week’s issue of the Journal, in Dr. Keen’s 
appeal to the medical profession, the names of the com-
mittieen appeared, but without the States from 
which they come. We now reproduce the names of the 
members of the committee as follows: James McMillan, 
Mieghan (chairman); J. H. Gallinger, New Hamp-
shire; H. C. Hansborough, North Dakota; Redfield 
Proctor, Vermont; J. C. Pritchard, North Carolina; 
Lucien Baker, Kansas; C. P. Wetmore, Rhode Island; 
C. J. Faulkner, West Virginia; Thomas S. Martin, 
Virginia; William M. Stewart, Nevada; Richard Ken-
ney, Delaware.

The Late Dr. Charles Inslee Pardee.—At the last 
meeting of the board of managers of the Manhattan 
State Hospital the following resolutions were passed :

Resolved, That this board, having learned from the 
report of the general superintendent of the death of 
Professor Charles Inslee Pardee, M. D., of the board of 
consulting physicians and surgeons of this hospital, 
places upon record its sense of the valuable services 
rendered by Professor Pardee to the hospital during 
his connection with its consulting board, dating from 
that board’s first organization in 1879, its sincere regret 
at their termination, and its sympathy for his family 
in their affliction.

Resolved, That the secretary be requested to enter 
a minute of the board’s action upon the records of the 
hospital, and to transmit a copy thereof to Professor 
Pardee’s widow.

Marine-Hospital Service Health Reports.—The follow-
ing cases of small-pox, yellow fever, cholera, and 
plague were reported to the surgeon-general during the 
week ending December 23, 1899:

The Death of Professor Puschmann.—We learn from the 
British Medical Journal for December 16th of the 
recent death, in his fifty-sixth year, from old-standing 
kidney disease, of Dr. Theodore Puschmann, professor 
of the history of medicine in the University of Vienna. 
Dr. Puschmann was a scholar of the highest order and 
a philologist of mark. His work on the History of Med-
ical Education has been translated into English by Mr. 
Evan H. Hare.
The Buffalo Academy of Medicine.—At the last regular meeting of the Section in Obstetrics, on Tuesday evening, the 26th inst., the following papers were presented for discussion: Cancer of the Cervix, by Dr. Charles E. Congdon, and The Difficulties a Young Doctor encounters in Obstetric Practice, by Dr. Nelson W. Wilson.

Change of Address.—Dr. George P. Biggs, to No. 39 East Sixty-third Street, New York.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending December 23, 1899:

AMES, H. E., Surgeon. Detached from the Norfolk Navy Yard and directed to proceed home and to be ready for orders to sea service.

BELL, W. L., Assistant Surgeon. Detached from the Independence and ordered to the island of Guam via the Scindia.

DAYS, F., Assistant Surgeon. Ordered to duty at the Naval Hospital, New York.

DUNN, H. A., Assistant Surgeon. Detached from Port Royal Naval Station and ordered home to await orders.

Elliott, M. S., Assistant Surgeon. Detached from the Vermont and ordered to duty at Port Royal Naval Station.

HARMON, G. E. H., Medical Inspector. Detached from the Brooklyn and ordered to the Baltimore.

LANGHORNE, C. D., Assistant Surgeon. Detached from the Monterey and ordered to the Princeton.

LOWNDES, C. H. T., Passed Assistant Surgeon. Detached from the Princeton and ordered home.

NORTON, O. D., Surgeon. Detached from the Solace and ordered to the Monadnock.

PERCY, H. T., Surgeon. Ordered to the Norfolk Navy Yard.

PERSONS, R. C., Medical Inspector. Detached from the Baltimore and ordered to the Brooklyn.

STOUTHAGHTON, J., Passed Assistant Surgeon. Detached from the Monadnock and ordered to the Bennington via the Solace.

WHEELER, W. M., Passed Assistant Surgeon. Detached from duty at the Naval Hospital, New York, and ordered to the Vermont.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending December 21, 1899:

WASDIN, EUGENE, Surgeon. Granted leave of absence for one month and fifteen days, to take effect on or about January 15, 1900.

WHITE, J. H., Surgeon. Detailed, under the provisions of the act of congress approved March 2, 1899, as a member of a commission to investigate the origin and prevalence of leprosy in the United States.

VAUGHAN, G. T., Passed Assistant Surgeon. Detailed, under the provisions of the act of congress approved March 2, 1899, as a member of a commission to investigate the origin and prevalence of leprosy in the United States.

STONER, J. B., Passed Assistant Surgeon. Granted leave of absence for seven days from December 23d.

ROSENTHAL, M. J., Passed Assistant Surgeon. Detailed, under the provisions of the act of congress approved March 2, 1899, as a member of a commission to investigate the origin and prevalence of leprosy in the United States.

TROTTER, F. E., Assistant Surgeon. To proceed to Toregas Quarantine and report to the medical officer in command for temporary duty.

KEYES, J. M., Acting Assistant Surgeon. Granted leave of absence for thirty days from December 16th.

TUTTLE, JAY, Acting Assistant Surgeon. Granted leave of absence for thirty days, to take effect on or about January 2, 1900.

COMPST, N. C., Hospital Steward. Relieved from duty on steamer Weehawken and directed to proceed to Louisville, Kentucky, and report to the medical officer in command for duty.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 16 to December 23, 1899:

CLAUSSON, WILLIAM W., Acting Assistant Surgeon, United States Army, will proceed to San Francisco for duty.

DEAN, ELMER A., First Lieutenant and Assistant Surgeon, United States Army, will report to the General Hospital, the Presidio, San Francisco, for duty.

REYNOLDS, FREDERICK P., Captain and Assistant Surgeon, United States Army, will proceed on the transport Summer, on or about January 15, 1900, to Manila.

WILCOX, STARLING S., Acting Assistant Surgeon, United States Army, is assigned to temporary duty at the General Hospital, the Presidio, San Francisco, awaiting transportation to the Philippines.

Society Meetings for the Coming Week:

Monday, January 1st: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Cornig, New York, Academy of Medicine; Utica, New York, Medical Library Association; Boston Society for Medical Observation; St. Albans, Vermont, Medical Association; Providence, Rhode Island, Medical Association; Hartford, Connecticut, Medical Society; South Pittsburgh, Pennsylvania, Medical Society; Chicago Medical Society.

Tuesday, January 2d: New York Neurological Society; Buffalo Academy of Medicine (Section in Surgery); Elmira, New York, Academy of Medicine; Ogdensburg, New York, Medical Association; Hudson, New Jersey, County Medical Society (Jersey City); Androscoggin, Maine, County Medical Association ( Lewiston—annual); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

Wednesday, January 3d: New York Academy of Medicine (Section in Public Health); Society of Alumni of Bellevue Hospital; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond, New York (New Brighton—annual); Penobscoft, Maine, County Medical Society (Bangor); Bridgeport, Connecticut, Medical Association.

Thursday, January 4th: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, New York;
Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington); Medical Society of City Hospital Alumni, of St. Louis; Atlanta Society of Medicine.

Friday, January 5th: Practitioners' Society of New York (private); Clinical Society of the New York Post-graduate Medical School and Hospital; Baltimore Clinical Society.

Saturday, January 6th: Manhattan Medical and Surgical Society, New York (private); Miller's River, Massachusetts, Medical Society.

Births, Marriages, and Deaths.

Married.

Lusk—Tiffany.—In New York, on Wednesday, December 20th, Dr. Graham Lusk, son of the late Dr. William T. Lusk, and Miss Mary Woodbridge Tiffany.

Shropshire—Steele.—In New York, on Wednesday, December 29th, Mr. Ralph Freeman Shropshire and Miss Sophomiba Preston Breckinridge Steele, daughter of Dr. Théophilus Steele.

Died.

Mason.—In Troy, New York, on Sunday, December 17th, Emilie Harding Mason, wife of Dr. William P. Mason.

Obituaries.

EDWIN R. AXTELL, M. D., OF DENVER.

Dr. Axtell was born in Washington, Indiana, February 7, 1866. After receiving his preparatory education, he studied medicine and graduated from the Miami Medical College, Cincinnati, in 1888. He served for a year as interne in the Cincinnati Hospital, in which position he discharged all his duties so faithfully and conscientiously, and proved himself so valuable to the attending physicians, that he gained many friends, and left the hospital at the end of his term beloved and respected by all.

Dr. Axtell went to Denver in 1889, and spent eighteen months as interne in St. Luke's Hospital, where the same industry, conscientiousness, and faithfulness characterized his work and treatment of patients, with his courtesy and loyalty to the attending physicians, that had attended his residence in the Cincinnati Hospital. After leaving St. Luke's Hospital he opened an office and began to devote himself to the use of the microscope in the study of histology, pathology, and the investigation of the micro-organisms. He did his work so thoroughly in this line that he was able to throw light on many subjects which were bothering his fellow-practitioners. He was pathologist to St. Luke's and the Arapahoe County Hospitals for five years, and at the time of his death was one of the attending physicians of the latter hospital. He was connected with the University of Denver, Medical Department, for a period of about eight years, first as lecturer on pathology, and for the last four or five years as lecturer on renal diseases. He was secretary and treasurer of the faculty for a number of years. He was the father of the Colorado Medical Journal, and its editor and proprietor from the first issue to the time of his death. His editorials were clean, spicy, and readable.

On December 1st of the present year, while making a post-mortem examination of the body of a patient that had died from sepsis, he cut his hand, and from this wound became infected and died two weeks later from the result of the poisoning.

Dr. Axtell was greatly beloved both by his patients and by his numerous friends among the medical profession. There has been no one that has been more loyal to his friends, more conscientious in his work, or more faithful in the performance of his duties than the lamented Dr. Edwin R. Axtell. His life was clean, his professional honor unsoiled, and he left us prematurely, just at the time when he had begun to reap the fruits of years of industry, toil, and the patient study of disease.

Pith of Current Literature.

The Place of Iodoform in Surgery.—Dr. Edmund C. Brush (Journal of the American Medical Association, December 16th), to answer the question, “Would surgery suffer if iodoform was abolished?” addressed a circular letter to one hundred representative surgeons holding recognized positions in medical schools respectively in London, Edinburgh, Quebec, Toronto, Montreal, and in twenty-two schools in the United States. The letter contained four questions: 1. What germcidal powder do you prefer? 2. Your second choice in germcidal powders. 3. Have you seen any bad effects from using iodoform? If so, what? 4. In your opinion would surgery suffer if iodoform was abolished? The author received eighty-four replies. The summary showed that twenty-seven surgeons used iodoform, twenty-four no powder of any kind, twelve boric acid, eight arsine, and thirteen various—e. g., acetanilide, nosophone, iodol, etc. As to effects, seventy-three had seen no bad effects, eleven had not—but four of the eleven did not use iodoform. The effect of the abolition of iodoform on surgery, according to thirty-seven, would probably be negative, while forty-seven considered that surgery would suffer. Of this latter class, twenty-seven think the detriment would be general, twelve limit it to surgical tuberculosi, and eight to its use in gauze and specific cases.

Dr. Brush considers that for the present the answer to the question proposed seems to be “Yes, to a very limited extent!” but he predicts that in five years the answer will be “No, not in the least!”

The Measurement and Capacity of the Bladder in Women.—Dr. Guy L. Hunter and Dr. Irving P. Lyon (Journal of the American Medical Association, December 16th) report the result of a series of investigations made at the suggestion and with the assistance of Dr. Howard Kelly to determine the measurements and capacity of the bladder in women. All experiments were made on healthy living women in the knee-breast posture, the rectum, vagina, and bladder being dilated by atmospheric pressure produced by opening these cavities to the outside air by the insertion of a speculum, after Kelly's method.

In the twenty-five women examined, the average bladder capacity by atmospheric distention was found to
be 303 cubic centimetres, individual cases ranging from a minimum of 160 to a maximum of 543 cubic centimetres. The capacity in general follows the general size of the bladder by internal mensuration, and also in a general way the size of the woman. Measurement was also made, in twenty-two cases, of the fluid content of the bladder, boric solution being used for this purpose. On anesthetized patients the solution was introduced through the double-barreled catheter until overflow occurred through the upper barrel; on those without anesthesia, until discomfort was caused to the woman. The average fluid capacity was thus found to be 429.7 cubic centimetres, varying in individual cases from a minimum of 210 to a maximum of 810 cubic centimetres. The fluid capacity of the bladder was thus found to be more than one third greater than the air capacity, a difference that would be expected because of the elasticity of the bladder walls under increased pressure.

The bladder, as a whole, when dilated with air and observed during operation within the pelvic cavity—from abdominal section—was found to be ellipsoidal in form, flattened somewhat in its antero-posterior diameter and increased transversely. The transverse diameter was always the greatest measurement. Mathematical calculation of the cubic content of an ellipsoidal viscus of the dimensions of the bladder corresponded closely with the actual air capacity obtained by expression.

The average length of the urethra in seventeen cases was 3.3 centimetres, the shortest urethra measuring 2.7 and the longest 4.2 centimetres.

The Question of Ocular Tenotomy.—Dr. E. H. Linnell (Journal of Ophthalmology, Otology, and Laryngology, October) concludes a paper on this question with the following aphorisms:

First. Send your patient to a thorough, careful, and conservative oculist.

Second. Be sure that all errors of refraction, even though slight, have been carefully corrected. The author is satisfied from his own experience that many nervous and asthenopic symptoms result from very slight refractive errors in persons of a susceptible nature, although he is aware that many oculists differ from him in this opinion.

Third. Be sure that the frames fit the patient's face properly.

Fourth. Be sure that a reasonable trial of systematic exercises for the development of the weak muscles, either with or without the use of electricity, has been made.

Fifth. If you have eliminated other sources of reflex disturbances, so that you are reasonably sure that the existing symptoms are directly dependent upon the heterophoria, advise tenotomy.

The Sterilization of Instruments with Boiling Distilled Water.—Dr. W. K. Roberts (Journal of the American Medical Association, December 16th) says, as a result of a series of experiments on the sterilization of cutting instruments, that if our ordinary hydrant water was used the edge of a knife was ruined, and in fact the whole instrument was damaged. The addition of soda to the water prevented the latter trouble, but only slightly lessened the harmful result to the edges. Rain water and the condensed vapor of the artificial ice establishments yielded less disastrous results, but still a knife boiled in these solutions, even with the addition of various preparations of sodium or potashium, was unfit for delicate use. As a consequence, inquiry of a large number of general surgeons elicited the information that, while instruments in general were usually prepared for operations by boiling, knives were simply scrubbed carefully, or scrubbed and dipped in alcohol. The efficiency of alcohol as a disinfectant has been so frequently questioned that its use seems almost superfluous.

The author's experiments proved that not only might instruments be safely boiled in distilled water a sufficient length of time to become sterile, but also, if distilled water was used in a sterilizer that was free from oxidized metal, the vapor and steam thus generated could be made use of for the preparation of instruments, dressings, and other appurtenances of an operation without harmful results to any of them, which would seem to be a convenience and to confer a simplicity greatly to be desired.

Some of the Mental Conditions in Fasting and Abstinence.—The British Medical Journal for October 7th says editorially that in a recent Thèse de Paris Dr. Lasignardie deals at some length with certain interesting questions regarding fasting and abstinence, and investigates the mental conditions resulting from total or partial abstinence from food. There are several sorts of abstinence to be distinguished from one another. First, there is the voluntary abstinence which may be undertaken by any one for "exhibition" purposes, and among instances of this sort should be classed the experiments of professional fasting men such as Sicci and Merlatti in recent times. A second category includes enforced abstinence from food during illness. A third of patients suffering from acute fevers, hysteria, and acute insanity. Another group includes cases of enforced privation, either from poverty and want, from shipwreck and absence of provisions, or from accidental entombment in mines, etc. A fourth class includes the rare instances where fasting has been determined on by persons with suicidal intent, as in the cases recorded of Viterbi and Guillaume Granie. Finally, the fifth and last group includes fasting as a religious observance. One of the most interesting chapters in the thesis is devoted to a study of the temporary mental delirium which may be produced by enforced privation, as in cases of shipwreck without provisions. A confidante of the author, Dr. Maire, was one of the unfortunate sufferers in the shipwreck of the French vessel Ville de Saint-Nazaire, and a very full account is given of his narrative regarding the délire d'inanition observed by Dr. Maire both as a personal experience and as observed among his fellow sufferers. The mental conditions produced by abstinence from food are summarized as follows: 1. There is noticed an activity of the intellectual faculties, and particularly of imagination, if the abstinence has not been too prolonged, and especially if it is voluntary and habitual. 2. In cases where abstinence has been pushed to a greater degree, there is found a change in character and in conduct, which may express itself in the forms of irritability of temper, excessive egoism or selfishness, and even cruelty. At the same time there may also be present distinct intellectual disturbances, such as diminution or partial loss of memory and of volition and self-control, and a tendency to sudden and irresistible impulses which are of an instinctive nature. 3. In more marked or grave cases there may supervene nocturnal mental trouble, such as disturbance...
or loss of sleep, distressing dreams and nightmares, illu-
sions and hallucinations of the senses, delusions and
dangerous impulses. 4. Diurnal mental disturbances,
when present, indicate a most serious and grave state
of affairs. Such disturbances may take the form of
agitated dreams, illusions, impulse, and delirium some-
times of an acute and dangerous type. 5. Finally,
under the influence of hallucinations, of delirium, and
of irresistible impulses, the patient may be impelled to
deeds of danger and of violence, which may have bear-
ings of medico-legal importance. In such cases the
estimation of the person's responsibility should be natu-
really dependent upon the consideration of the mental
disturbances present, and on their gravity. It is pos-
able to establish a parallel between the mental state
resulting from abstinence and that from self-intoxica-
tion. The differences met with are but slight; the same
general alterations and disturbances of intelligence, of
morality, and of conduct, the same nocturnal disturb-
ances, and in marked cases the same diurnal mental trou-
bles are found in both classes of cases. Clinical and
experimental facts accord in showing that the phenom-
a of self-intoxication exactly resemble those result-
ing from abstinence and deprivation of food.

Apomorphine in Acute Alcoholic Delirium.—The
Canadian Practitioner for December, quoting Merck's
Archives, says that Tompkins calls attention to a new
use to which he has several times success-fully put apo-
morphine hydrochloride. He says that in cases of acute
alcoholism with delirium it "gets in its work in min-
utes, whereas it takes hours for bromides, chloral, and
the like to have effect." He considers it far superior to
morphine in such cases, as it eliminates the poison,
while morphine dries up the secretions. Its use is, how-
ever, generally contraindicated in genuine cases of
delirium tremens, because there is usually weakness of the
heart. In one case the author, being called about mid-
night to see a man in convulsions, from his knowledge of
the man's habits and the odor of liquor in his breath,
easily made the diagnosis, and he at once injected hypo-
dermically a tenth of a grain of apomorphine hydro-
chloride. In four minutes free emesis occurred, rigid-
ity changed to relaxation, and excitement to sleep.

Paralysis in Whooping-cough.—According to the
Canadian Practitioner for December, an inquiry into
this condition has been carried on by Homind, and pub-
lished in a Paris thesis. Paralyses in whooping-cough
he finds to be infrequent, appearing usually in severe
cases occurring in young children. He divides them into
tree classes: 1. Paralysis of cerebral origin; the most
frequent, constituting about forty per cent. These may
assume the form of coma or of apoplexy, and may be of
the hemiplegic type. Epilepsy may follow as a compli-
cation, or aphasia. In rare cases the special senses may
be affected, giving rise to hemisopia or blindness. 2.
Bulbar paralysis. Sometimes there is a simple para-
plegia, and sometimes the picture resembles Fried-
reich's or disseminated sclerosis. 3. Paralysis of peri-
ophetal origin. A few cases of this form are known.
These paralyses may be traced to two causes, infection
and vascular strain.

The Restlessness of Old Age.—Dr. Clement Dukes
(British Medical Journal, December 2d) describes a
condition in old people who are frequently a burden to
themselves, and who occasion considerable distress to
the friends who look after them by their incessant
restlessness by day and by night. During the day they
are never quiet. If they sit down they want to get up
and walk about. Then they sit down, and in a few min-
utes are on the move again. This want of peace is very
wearing to themselves and those who live with them.
During the night they are merely restless, and toss and
turn about in bed; or sleepless; or they have to sit up in
bed or in a chair, with dyspnea. Consequently they
arise in the morning unrefreshed and unrested to re-
sume the day performance.

This arises, in the author's opinion, from the grad-
ual age-failing of the scavenger organs. Their incom-
petence fails to depurate the blood sufficiently. And
this lack of perfect removal of the products of wear
and tear occasions increased arterial tension. Hence the
restlessness.

The administration of carminatives, sedatives, or
digitalis merely aggravates the condition. The remedies
which bring calm and peace, and remove all the discom-
forts, are those which relieve the arterial tension,
such as nitroglycerin, one one-hundredth of a grain, and
even better still, because it requires to be taken less
often, erythrol tetranitrate, half a grain to a grain.

The "Laveran Body" in Birds and the Mosquito
Theory of Malaria.—Lieutenant-Colonel E. Lawrie
(Indian Medical Gazette, November), of the Indian
medical staff, as the result of experiments performed
on birds in the laboratory of the Hyderabad Medical
School between September, 1898, and September, 1899,
arrives at the following conclusions:
1. The so-called 'halteridium' is the halter-
shaped, Laveran showed, Laveran body in birds.
2. No form of the Laveran body, avian or human,
can be isolated or cultivated. All the known facts show
that it is not a parasite, and as it fulfills none of Koch's
canons, it can not be a pathogenic organism.
3. Neither the plasmodium nor the proteosoma
possesses the function of reproduction.
4. Our experiments show that in birds the Laveran
body, proteosoma, is a product of the blood, developed in
the red blood cell, and not producing any deterioration
in the health of the bird. It can be destroyed by
inoculation from bird to bird, is not infective, and does
not multiply in the blood.
5. Seeing that the Laveran body, the plasmodium
or the proteosoma, is not a parasite, and that it can not
be reproduced by experimental inoculation, it is unlikely
that it can be reproduced by a mosquito bite. There is
no ground for supposing that the passage of the prote-
osome through the mosquito, granting this to be possible,
could render it infective. If it could, the true cause of
malaria would be the mosquito and not the 'parasite':
this is, of course, absurd.
6. Ross's mosquito theory of malaria is based on a
series of assumptions and not on facts. One of these is
the assumption which was originally put forward by
MacCallum, of Baltimore, United States of America, and
adopted without examination by Manson and Ross, that
the flagellum is the male and the hyaline cell the female
clement of generation in the Laveran body in birds.
Now, the plasmodists say that the rosette is a sporulating
body, and that the formation and liberation of spores
by the rosette is the method by which the reproduction
of the Laveran body is effected. Our discovery of the
rosette in cow's blood proves that MacCallum's assump-
tion at all events is false, since it is evident that even if
the proteosoma were a parasite, it could not be reproduced in two entirely different ways. On the other hand, the rosette is proved not to be a sporulating body in birds’ blood by the fact that its ‘spores’ are a great deal larger than the speck in the red cell, which is the form in which the proteosoma first appears in the blood. Another of Manson’s and Ross’s unwarranted assumptions is that it is possible to infect birds with proteosoma by mosquito bites. To have made his position tenable, Ross ought first to have shown that the birds he believed he had infected with proteosoma by mosquito bites would not have got them if they had not been bitten by mosquitoes at all. Our experiments have clearly shown that you can never be certain that birds of the class in which proteosoma are found—such as sparrows, crows, and pigeons—will not develop them spontaneously, and Ross’s manifest ignorance of this fact entirely vitiates his inoculation experiments, as well as the conclusions he has drawn from them.’

Upon this paper the Gazette comments editorially as follows:

“We have much pleasure in publishing in this issue the results of a long series of careful experiments done in the laboratory of the Hyderabad Medical School under the direction of Lieutenant-Colonel E. Lawrie, I.M.S. Though the mosquito malarial theory is fascinating and has been accepted more or less by many medical men, it is no reflection on them if we say that the majority of medical men are not in a position to judge for themselves; for instance, it has been already pointed out in these columns that assumptions are not facts, and it is well known that, although there are many facts in favor of the malarial mosquito theory, yet it is still little more than an hypothesis, and there are several gaps in the theory which are by no means filled up, even by the researches of the Italian observers. Therefore we welcome intelligent criticism, such as the Hyderabad Laboratory sends us, and their conclusions deserve the fullest consideration at the hands of workers at this fascinating theory. We are sure that Dr. Lawrie would only be too glad to offer the use of his laboratory to any medical man who wishes to confirm or, it may be, confute his results. In fact, the government might, with very little cost or trouble, order a small skilled committee to assemble at Hyderabad to examine the specimens and test the results of the work done in this subject. Such a committee could easily be formed from medical officers of both services in Madras; there are several men there who have done work in this direction, and who are skilled microscopists.”

The Operative Treatment of Uterine Fibroids.—Dr. F. A. Lockhart (American Gynecological and Obstetrical Journal, December, 1890) sums up a paper read before the Vermont State Medical Association as follows: 1. A uterine fibroid should not be interfered with unless it is giving rise to serious symptoms, be they mental or physical, notwithstanding the statement of one gynecologist (Gordon, American Journal of Obstetrics, vol. xxxi, 1895) that he removes all fibroids which he meets with in practice, whether they are causing trouble or not. 2. Curetting is merely a palliative measure, as is also, in many cases, ligation of the uterine arteries. 3. Removal of the appendages ought to be merely a dernier ressort, as it practically never cures and does not always even relieve. 4. The operation of selection should be either total hysterectomy or else myomectomy. 5. Myomectomy is to be chosen (a) where the tumor is sub-

the peritonajum. Where it is not possible to excise the lesion, the morcelleraent of the fibroid is the only method of relief. 6. Total hysterectomy is indicated (a) where the tumor is submucous and pedunculated; (b) where it is subserous and either has a pedicle or a well-defined border; (c) where several small nodules lie immediately beneath the peritoneum. 6. Total hysterectomy is indicated (a) where the tumor is submucous and non-pedunculated, and the cervix can not be dilated sufficiently to allow of morcellation; (b) where the tumor is either interstitial, large and subserous without a pedicle, soft, fibro-cystic, or undergoing degeneration; (c) where the tumor is complicated by diseased annexa.

Rat’s Tail Sutures.—M. E. Janes (Gynecologie, Octobe-15th; Lyon médical, November 5th) says that in a rat’s tail are found a number of tendons, from six to seven inches long, very fine yet very strong. They are obtained as follows: At some distance from the root of the tail the skin is cut in a circular fashion and reversed like a glove. By scratching with the nails in the neighborhood of the last vertebra a delicate bundle of from five to six tendons can be detached the whole length of the tail, from each one of which two or more threads can be drawn. The author says that if the dissection has been properly made, the hands as well as the rat’s tail having been previously sterilized, the threads are aseptic and may be used as they are. They may be preserved dry or in alcohol. They are well absorbed, and they form a very practical suture for delicate, especially ophthalnic, surgery. They are easily threaded.

Glycosuria in an Infant Twenty-two Months Old.—M. Le Gendre (Gazette hebdomadaire de médecine et de chirurgie, November 23rd) recently reported to the French Society of Pediatrics the case of an infant twenty-two months old, the son of parents respectively gouty and arthritic, which, in spite of a considerable appetite, had been wasting for some time. A general examination disclosing no cause, M. Le Gendre examined the urine, and found 13.87 grammes of sugar to 750 grammes of urine. The diabetes was acute, acetotonia ensued, and death by coma occurred in about two months.

Vicarious Menstruation from the Gums.—Dr. W. George Beers (Dominion Dental Journal, November) reports that he has had a very complicated case of contraction of the superior and inferior teeth to contend with in a patient aged seventeen, which afforded an opportunity for observing a very interesting case of vicarious menstruation. The day after he had taken the impression for models, the patient came by appointment, and he noticed such an effusion of blood, about the gingival margins especially, and the gums generally, that at first he suspected that the blood in the mouth came from the lungs. But upon careful observation there was no mistake about the matter, and the surprise was the greater because the gums were healthy and the teeth free from caries or calculus. A week afterward Dr. Beers inserted the apparatus for expanding the superior arch. It was worn with comparative comfort until the periodical return of the menses, when the margins of the gums—which the plate did not touch—were inflamed, as if by the rough inner edges of a badly fitting vulcanite plate, and the bleeding reappeared. Upon examination of the apparatus there was no exciting mechanical cause to produce such a result, and he was at a loss for an explanation until he found that the blood was non-congealable, and that the same symptoms of hysteria were present as had been observed the previous month. The author then made it his duty to extend his inquiries, and’
learned that the condition was regularly present each month, associated with severe migraine, and that the bleeding began and ceased coincidently with the recurrence and cessation of menstruation. At the time of writing the ninth observation had been made.

Recovery after Drinking Aconite Liniment.—Dr. W. A. Potts (Edinburgh Medical Journal, December) records the case of a man, seventy-five years of age, who accidentally drank half an ounce of the official aconite liniment, B. P. The treatment consisted of a tumblerful of warm water with a teaspoonful of mustard in it, followed almost immediately afterward by another tumblerful of warm water containing a tablespoonful of salt. These were promptly administered by his wife and were followed by free emesis and purging.

Dr. Pott's treatment, on arrival, consisted in getting the patient to bed with hot bottles, and in the administration subcutaneously of a fourth of a grain of strychnine, followed after an unspecified interval by another similar injection and, when the vomiting had stopped, by an ounce of whisky per os. The poison had been taken at 3 A.M., and by 9 A.M. the patient was well enough to eat his breakfast. The next day he was all right.

Letters to the Editor.

UNPLEASANT EFFECTS OF ORTHOFORM.

Clatville, N. Y., December 6, 1899.

To the Editor of the New York Medical Journal:

Sir: In the issue of the Journal for November 25th Dr. G. E. Decker, of Davenport, Iowa, cites two cases of dermatitis following the use of orthoform which are very interesting, as they go to prove that there is still much to be learned in regard to this peculiar drug. Aside from the following case, invariable good results have followed the use of orthoform in my practice. My experience was similar to Dr. Decker's and his article in your Journal threw some much-needed light on this case, insomuch as I was in doubt as to the true character of the disease.

A machinist, twenty-eight years old, came to my office with suggestive cellulitis of the right forearm following an injury and infection of the hand. The suppuring foci were slit up and thoroughly cleansed with peroxide of hydrogen and 1- to 2,000 bichloride solution, and dressed with orthoform powder. These dressings were repeated every day for a week, the arm doing well. At the end of this time there appeared a peculiar dermatitis surrounding the incisions, which spread rapidly until nearly the whole arm was involved. The surface appeared red, swollen, and covered with small confluent blisters containing a sticky, serous fluid. After a few days many of the blisters coalesced and broke, drying up and leaving a yellowish crust. A peculiar branny odor emanated from the involved surface. There was no pain on pressure or manipulation, but the most intolerable itching was constantly complained of, and at one time the patient became nearly delirious from this cause. There was some slight elevation of temperature.

After many remedies had been tried without any result, hot applications of witch hazel were used, when the itching immediately ceased and the dermatitis slowly disappeared.

During the first stage of this disease the appearance was very similar to that of the dermatitis caused by Rhyns toxicodendron poisoning, but as it progressed all similarity ceased. H. H. Wilson, M. D.

Book Notices.

The first change which is to be noticed in this new edition is that the name of Charcot is now missing from the editorial board, though retained as a sort of memorial on the title-page. The editors of the new edition appreciate what a loss to medicine the death of Charcot has been, but they have endeavored to carry out, as his pupils, the ideas which were his and have tried to revise and complete this new work without changing its general plan and scope.

The first volume contains a general survey of bacteriology and the pathology of infection, including diseases common to men and animals, and the diseases classified as disorders of nutrition; the most important of the latter are gout and diabetes. Guignard has found but little that is novel to add to the general subject of bacteria. He clings very closely to the older views of the complete identity of the bacterial species, and evidently looks with some doubt on the recent reports of Buchner concerning the close resemblances between the Bacillus anthracis and the Bacillus subtilis when cultivated on suitable media. However, he admits that very remarkable alterations can be produced temporarily in the bacterial economy, especially in the more easily observable points of difference, such as the production of gas, the formation of pigment, etc. Charrin, in his section on the general pathology of infection, has found much to change and much that is new to add. Almost entirely new ideas have arisen and have been accepted during the seven years between these two editions, on the theory of the interaction of toxin and antitoxin, on the localization of the toxic action on the cells, and on the germicidal action of the tissues. We miss, however, a full discussion of the "lateral-chain" theory of toxin action recently broached in Germany.

The section on diseases of nutrition has been much altered and brought more closely in line with the present pathological trend, though it seems strange to see a general heading of "acid dyscrasias" to include rickets, osteomalacia, etc.

The most important article in the second volume is that by Chantemesse on typhoid fever, which is, indeed, a model of accuracy and completeness. All the recent studies which have been made under the stimulus of the discovery by Widal of the agglutinative property of typhoid serum toward typhoid bacilli have been considered and reviewed, and nothing of importance seems to be missing. We regret that the same praise can not be
given to Widal's own article on malaria, which might well have been written ten years ago, so little has it been brought up to date.

The chapters on diphtheria and erysipelas, on the other hand, are excellent, and prominence has been given to the modern forms of serum treatment. While the use of an antitoxic serum in diphtheria has been followed by such a great diminution in the mortality, an equal advance can not be recorded in the use of a streptococcus serum in erysipelas. At present, after a trial of some years, the actual change in the mortality statistics is so slight as to be entirely within the limits of error due to the moderate number of cases observed and the natural variations in the severity of the disease. It must be said of the work that the two volumes so far issued give great promise for these yet to be published and show that the revision has in many cases been most thorough.

Much attention has recently been paid to the conditions of wound healing, the value or harmfulness of antiseptic solutions, and the possibility of obtaining an absolutely sterile field during an operation on a non-infected patient. The author of this monograph has tried to answer these and other questions. He rightly criticises the results obtained by Schimmelbusch when the latter infected fresh incisions in susceptible animals by fresh and virulent cultures of the anthrax bacillus. These germs were found to be carried into the circulation in a few minutes and quickly produced death in the animals. Such an infection with a pure culture is not met with clinically, and no general conclusions can be drawn from experiments of the sort in question. The problem has recently been solved by showing that, if a fresh incision is infected by dirt, scrapings from clothing, bits of cloth, or similar infectious material, not only do the germs enter the blood only after some hours' time, but they enter in such small numbers at a time that they can easily be disposed of by the tissues. Another point made by Pascale is that the ordinary pus cocci may circulate in considerable numbers in the blood for a short time without setting up any reaction, a thing impossible in the case of anthrax bacilli. He finds that all wounds are infected to a certain degree, even those commonly called sterile, and that a moderate infection is perfectly compatible with primary union of the wound without any noticeable elevation of temperature. The recent strivings for complete asepsis by the use of sterile gloves have indeed removed one formidable source of infection, the hands of the surgeon and his assistants, but they do not alter the fact that the edge of the wound is bordered by the infected skin of the patient. If the surgeon can not absolutely sterilize his hands by prolonged scrubbing, how much more difficult it must be to remove the germs from an axilla or a scrotum!

In infected operative wounds it is of distinct advantage to wash them out with an antiseptic solution, says the author, as the virulence of the germs present is distinctly reduced and the danger of their setting up a progressive infection is minimized, even though their absolute destruction is not accomplished. This result is best obtained if the antiseptic is used in the first twenty-four hours. Progressive phlegmonous inflammation can almost always be avoided if the wound is properly opened and irrigated. A few histories of cases are appended as illustrations, and a table of the results obtained on animals closes this interesting monograph.

The results of the author's experiments on bone grafts are that the best hope lies in the filling of the gap by bone formation from the periosteum; that all fragments of bone separated from the periosteum, as well as all trophine buttons, undergo necrosis first and then may be partly absorbed and partly regenerated, the regenerative process beginning in the uninjured bone outside of the fragment and extending only a short distance into the latter. Decalcification of the button before replacement is of no value. The remains of the necrosed button or a metallic plate may be firmly encapsulated in the bony and fibrous tissue and perfectly protect the soft parts beneath.

Conferencia sobre a febre amarela realizada pelo Dr. Domingos Freire.

The lecture contained in this pamphlet is devoted to a rather sharp criticism of the contents of Sanarelli in regard to the bacillus discovered by him in the bodies of the persons dead of yellow fever, the so-called Bacillus icterioides. No new facts are brought forward, but the writer repeats his allegations for the coecus discovered by himself, and ends in a bitter personal attack on Sanarelli because he inoculated hospital patients with pure cultures of the Bacillus icterioides and thus produced very severe yellow fever. Dr. Freire holds that such a procedure is cruel and entirely unjustifiable, inasmuch as the specific effect can be observed in animals.

Miscellany.

The Resistance of Microbes to Temperature.—Dr. Felix Vitale (Medical News, December 2d) concludes a very interesting paper on this subject as follows: We may say that the temperature exerts an influence on microbes which bears a direct relation to the media in which they are being cultivated, and the resistance they offer is just so much greater as the media on which they live, whether natural or artificial, are favorable to the vitality of the microbes.

An Indian Description of the Difference between a Carbuncle and a Boil.—Dr. Charles Milton Buchanan (St. Louis Courier of Medicine, November), in an exceedingly interesting article on Some Medical Customs, Ideas, Beliefs, and Practices of Snonohimish Indians of Puget Sound, says that among these Indians carbuncle used to grow to an inordinate size, was very common, and was frequently fatal. One old Indian described it to him as a “big boil that was not a boil, but is bigger and has many eyes instead of just one eye, as the boil has.”

The Grinding Tyranny of the Sanitary Oligarchy.—The Southern Medical Journal for December, 1899, gives utterance to the following wail from the downtrodden public:

“We have boiled the hydrant water;
We have sterilized the milk;
We have strained the prowling microbe
Through the finest kind of silk;
We have bought and we have borrowed
Every patent health device,
And at last the doctor tells us
That we’ve got to boil the ice.”

Vicarious Philanthropy.—Dr. H. V. Sweringen, in a letter on Physicians and Charity published in the Cincinnati Lancet-Clinic for December 16th, discoursing on the simple methods so often practised by the tender-hearted laity of being charitable at other people’s, and especially physicians’, expense, says: “I have frequently been called into wealthy Christian (?) families, whose annual foreign missionary contribution was quite respectable in amount, to treat the ‘hired girl’ or ‘servant.’ Before seeing her, the dear, good Christian mistress of the house was certain to remind me that the girl was poor, entirely destitute, an orphan, had no one to depend on but herself; that her wages were barely sufficient to keep her when able to work, to say nothing of her inability to earn any while sick, etc.; that she was an excellent girl, of good moral character, and a splendid worker; that she was very desirous of keeping her, for good girls were very scarce now, but that she could not possibly keep her if she was going to be sick any length of time. ‘Poor girl! I feel very sorry for her, but I don’t know what I’m to do with her sick on my hands; if she is to be sick more than a day or two, doctor, can’t she be taken to the hospital, or to the county asylum? I can’t afford to keep her if she is sick. You do what you can for her, doctor; try and get her up as soon as possible, and she may be able to pay you some day.’

‘Thus are the remarks of the mistress ostensibly in the behalf of the ‘poor hired girl,’ but it does not require a very great stretch of the imagination to conclude that they are made principally in her own behalf, with the view of getting as much service from the doctor as possible, with the implied understanding that she would be in no way responsible for the same, and with the implied hope that the doctor would not expect the ‘poor hired girl’ to be.

‘The good (?), kind (?), charitable (?), Christian (?) mistress thus succeeds in securing professional services, and, perhaps, also the medicine, if the physician furnishes his own remedies. In every case, however, into which my curiosity prompted me to inquire every cent of money paid for medicine and every minute of time lost by sickness and failure to work was deducted from the ‘poor girl’s’ wages when, after recovery, she resumed her work. The physician may be as imperious as his patient, but that makes no difference to these charitable (?) Christians (?). Such Christianity is damnable. Hell is full of just such Christians. They are so close that it would be impossible to introduce a greased flaxseed into their recta rectorum.’

‘No wonder that girls go to the bad when they find so little of the milk of human kindness in Christian families!

‘I used to think it was the ‘whole thing’ to give a dollar to the tune of Greenland’s icy mountains, but I will never give another d—d cent to it until America’s abused, poverty-stricken hired girls are better treated by our Christian (?) civilization (?). I would much prefer to contribute five dollars to that other tune—

‘Als! for the rarity
Of Christian charity
Under the sun.
Oh, it was pitiful,
Near a whole city full.
Home she had none.’

Specialism Extraordinary.—The American Medical Compend for December quotes Dr. Kyle as saying:

‘We need more general medicine in specialism. There is such a thing as the specialist becoming too special, as is illustrated in the somewhat exaggerated story of the man who consulted the surgeon for the re-
of their fellow officers and a part of their escort; their object, it is said, being to create an empire in the heart of the Dark Continent. Very little is known of this malady, though it is supposed by the scientists of Europe to be a form of insanity caused by the tropical heat and malaria. According to the best description given of the disease at present, its first symptoms are a strong form of ennui and mild fever. A moral and mental derangement follows, which assumes different phases in different individuals. One may be so affected that he will shout and yell and fire off his pistol repeatedly at any object that seems to disturb him. In other cases the victim may insist on going about clad in dark, heavy clothing in spite of the heat. In every instance, however, the sufferers become erratic and irresponsible and are possessed of a frightfully savage temper. Even men who are the mildest mannered persons under ordinary circumstances develop intense quarrelsomeness under the influence of this strange disease. Several French and English physicians have described instances in which whole companies have been afflicted with la Soudanite, and express the opinion that it is epidemic. They have known of different occasions when entire expeditions have stopped in the desert of Sahara and wasted valuable hours in a senseless dispute over the most unimportant matters. While the disease may possess unique features when seen in Africa, it is undoubtedly practically the same ailment that often rages in other countries. In Asia it is often seen and is of particularly frequent occurrence in the Philippines, where "running amuck" is a common enough incident. Although not generally known, the possibility of the breaking out of such a disease among the American troops has been seriously considered by the government, and an expert has been appointed to make special study of the question in hope that he may be able to discover a remedy that may be used should the trouble appear among our soldiers. In the same manner, the English government has assigned physicians to study the curious malady.

The Editorship of the Ufficiale Sanitario, Rivista d'Igiene e di Medicina Pratica.—We learn from Naples that Professor Alfredo Rubino, whose conduct of this periodical has been eminently praiseworthy, is compelled by the increase of professional and professorial labors to relinquish the editorship.

What Constitutes a Surgical Operation?—The careful definition of this term is evidently much to be desired, for we learn from the British Medical Journal for November 11th that even nail-cutting may be judicially so declared. Some time ago, says the Journal, a German court had to adjudicate on the question whether corns constitute a disease. A still more abstruse problem has recently engaged the attention of a Vienna tribunal. A medical practitioner of that city, having occasion to operate, very properly trimmed his nails as a preliminary. In doing so, however, he cut his finger, but was nevertheless able to perform several operations on the same day. The wound became infected, and the practitioner himself had to be operated on. He was thus disabled for twenty-one days, and therefore claimed five florins ($2.50) a day from an accident assurance company. The company repudiated liability, on the ground that, according to its by-laws, no claim could be entertained for an operation performed by a medical practitioner on himself. The question whether nail-cutting is a surgical operation appears to have proved

The Other Side to the Automobile.—The Medical Age for December 10th, in an editorial note, says of the physician's automobile:

"A physician living in a picturesque part of England has recorded his experiences with the autocar. Its advantages for the physician he considers obvious. It saves time and fatigue; it can be got ready in about the time that a collar can be put on; it does not tire, and it will come out afterward as well as morning; it is not eating except when at work. At the same time an extract from this physician's diary shows that the automobile is not all that it should be; for instance: July 11th, changed battery. July 12th, wheels off; ball broken; new asbestos joint. July 23d, chain came off. July 24th, chain adjusted by engineer. July 25th, front wheel to works; split cone. August 4th, brake catch broken. August 11th, changed battery. August 12th, chains came off. August 14th, ditto; new chains (English). August 22d, countershaft off; squeaking. August 28th, changed battery. September 15th, water tube repaired; leaking. September 16th, changed battery. September 20th, ditto. September 20th, chains adjusted. September 21st, car to works, ten miles off; sundry repairs. September 22d, ditto; new belt. Had been in a bit of a puzzle here. Car would not take high-speed belt. Found at last that carrier did not carry slow-speed belt off working pulley, consequently on putting on fast speed I was industriously trying to run the car at two speeds at the same time—with unsatisfactory results. October 3d, chinese insulator worked loose; just managed to get car home. New insulator. October 8th, changed battery. October 10th, exhaust spring eased. October 17th, changed battery; cells out of order. Something better than this will have to take place before the automobile will displace the doctor's horse."

Practical Native Sympathy for the Wounded Soldiers in South Africa.—The contagiousness of civilizing influences is well shown by the correspondent of the British Medical Journal for December 9th who, under the heading The Sympathy of the "Brown People," says: "A very touching instance of the quiet sympathy of the colored people ought to be mentioned. A largely attended meeting of colored men was held at Stellenbosch, a very hot Bond centre, but where the brown people are enthusiastically loyal, to consider the best way of helping the imperial authorities, and it was decided to forward regularly supplies of strawberries and other fruit to the hospital. Stellenbosch is a large fruit-producing centre, and most of the colored folk have their little gardens. No white man was present at the meeting, and the action was absolutely spontaneous."

La Soudanite, a Newly Described African Disease.—According to the Southern Medical Journal for December, the School of Tropical Medicine of England is investigating a strange mental disorder that affects the white men in the tropics. The incident that is directly responsible for bringing attention to this trouble is the latest military scandal in France. Captain Valuet and Captain Chanoine, in the heart of the French Soudan, fired upon the flag of their country and also killed two
too much for the judicial intellect, for, after hearing arguments on both sides and suffering much vexation of spirit, the court reserved its decision. The Journal does not presume to offer any help toward the solution of so subtle a question. It ventures, however, to submit that, if nail-cutting comes within the sphere of operative surgery, a *a fortiori* shaving must do so, for that procedure was once among the duties of a surgeon. So well was this recognized in some countries that at the beginning of the present century some English surgeons were summarily dismissed the Danish naval service for refusing to act as barbers to the crews of their ships.

The Need of a Country Branch for the New York Orthopaedic Dispensary and Hospital.—In concluding his forthcoming annual report, the surgeon to the hospital, Dr. Russell A. Hibbs, will say in substance:

It is because of the perfection of the mechanical means now used that the time seems opportune for taking the next step and placing these patients in surroundings where those means may be most effective. As the condition of the general health measures for in instances the success of the mechanical treatment, the relief of the joint remaining permanent or otherwise as is the general constitution, it is in consideration of this matter that the answer to the question lies.

The principle above stated is well recognized by the profession and the public at large as applied to the treatment of tuberculosis of the lung. Evidences of this are seen in the work that is being done both in this country and in Europe in establishing sanitariums in the best atmospheric surroundings. By such means the number of patients cured will undoubtedly be greatly increased. This being true in regard to the disease when in the lung, it is still more true in the treatment of the same disease of a joint, in which the prospects of recovery are so much better.

That it is unwise to place a healthy child in the wards of a hospital for a long time is recognized by those who understand the essentials of health; and they will no less recognize the error of thus confining a child suffering from joint tuberculosis, a disease peculiarly characterized by its destructive effect upon the general constitution, and depending for its cure in all cases so largely upon reestablishing the best possible conditions of the general health. Neither should these children be sent back to their home surroundings.

There is but one solution to this problem. Establish a place in the country, in a healthy locality, near the city, where the patients with joint tuberculosis may be sent and remain until they are cured. The percentage of cures would undoubtedly be greatly increased, their permanency secured, and the duration of the treatment much shortened.

At the same time the education of such children may be accomplished. While this work is now carried on in the hospital to a degree of much usefulness, it is of necessity incomplete, for these patients must go home in a comparatively short time. From the nature of the disease it is also unwise, even when possible, for children so suffering to spend hours each day in the atmospheric surroundings of a crowded city schoolroom. They may also be taught an occupation, and thus be enabled to return with their health restored and an education sufficient to make them self-supporting men and women.

By this addition to the work, the equipment of the institution would become equal to the demands made upon it. It would then be necessary for this class of patients to remain in the hospital but a short time for the adjustment of apparatus, etc., when they would be sent to the country, thus making room for the admission of those coming to us now suffering from the deformities of non-tuberculous origin, who are in need of hospital treatment for short periods, but who in the majority of instances must be turned away.

The Durability of the Plaster-of-Paris Jacket.—At a meeting of the Section in Orthopaedic Surgery of the New York Academy of Medicine held on November 17th Dr. Stokes reported a case of Pott's disease in which the plaster-of-Paris jacket had been applied no less than 70 times, at intervals of from eight to fifteen months, and without causing pain or discomfort, although at the last application it was found that a small stone had made its way under the jacket and caused an erosion. This, however, had healed in a few days. Dr. Townsend said that he had known plaster jackets to be worn for two years.

The Craig Colony for Epileptics.—A board of consulting physicians and surgeons has been constituted as follows: Neurologists.—Dr. M. Allen Starr and Dr. George W. Jacoby, of New York, Dr. Henry Hun, of Albany, and Dr. James W. Putnam, of Buffalo. Surgeons.—Dr. Charles McBurney, of New York, Dr. Roswell Park, of Buffalo, and Dr. John W. Whitbeck, of Rochester. Physicians.—Dr. Charles E. Jones, of Albany, Dr. Charles Cary, of Buffalo, and Dr. William S. Ely, of Rochester. Orthopaedic Surgeons.—Dr. Henry Ling Taylor, of New York, and Dr. Louis A. Weigle, of Rochester. Ophthalmologists.—Dr. Lucien Howe, of Buffalo, Dr. Wheelock Rider, of Rochester, and Dr. George M. Gould, of Westfield. Gynaecologist.—Dr. Matthew D. Mann, of Buffalo. Pathologist.—Dr. Ira Van Giesen, of New York. Bacteriologist.—Dr. Harlow N. Brooks, of New York. Psychologist.—Dr. Boris Sidis, of New York. Pathological Chemist.—Dr. Christian A. Herter, of New York. Dentalist.—Dr. Charles J. Mills, of Mount Morris.

Osteopathy Declared Unlawful in Pennsylvania.—The Columbus Medical Journal for November 30th states that the Medical Council of the State of Pennsylvania, decided, on May 24th, that the practice of osteopathy within the State was illegal, and that those engaged in it were amenable to the law.

The Chair of Pathology in the University of California.—According to the Western Medical Review for December 15th, Dr. E. A. Taylor, formerly of the Pepper Laboratory of Clinical Medicine, Philadelphia, has been elected to the chair of pathology in the University of California.

The Investigation of Beriberi.—According to the Western Medical Review for December 15th, Dr. Hamilton Wright, an alumnus of McGill University, and late registrar of the Royal Victoria Hospital, Montreal, has been commissioned by the British government to spend the next three years in the Straits Settlements investigating beriberi and other tropical diseases.

Osteopathy in Georgia.—According to an Atlanta dispatch in the New York Times for December 24th, Governor Candler on the 21st inst. vetoed a bill passed recently by both houses of the general assembly providing for the practice in the State of Georgia of osteopathy.
